Although many women have rectal gonorrhea, the infection has not been given much attention in the United States. A survey of current textbooks on venereal diseases discloses that it is mentioned briefly if considered at all, in numerous standard treatises on gynecology it is not even mentioned, in one of the most recent its discussion is limited to three lines. Although scant attention has been given to the subject in English literature, a number of theses have appeared on various aspects of rectal gonorrhea in continental publications, especially during the last five years in the German.

Bruno Peiser³ credits Hecker⁴ with first describing the disease (1789). Hecker considered unorthodox intercourse the common cause. Foerster⁵ (1860) called attention to "rectal catarrh," which he thought often was due to gonorrhea. After Neisser's discovery of the gonococcus (1879) there was more interest in the disease. The majority of the reports dealt with its frequency in women. In recent German literature there is general agreement that rectal gonorrhea is a common concomitant of female genital gonorrhea, that the incidence is high, that it is easily overlooked and that the gonococcus can retain its virulence in the rectum for more than a year. Bickel and Abraham⁶ state that in fifteen cases, if histories as given by the patients are accepted as correct and reinfection is ruled out, "even after gonorrhea of the genitalia has remained cured for more than ten years, gonococci still may be found in the rectum."

Hayes⁷ published the first paper in English to deal with the important rectal aspects of the disease, and Rosser,⁸ in a paper on venereal disease of the anus and rectum, discussed the disease as seen in twenty-five of his cases. He states "In the United States the disease has continued to be regarded as a rare and self-limited

complication, requiring no attention except for a short period of palliation in those cases (the minority) in which unusually severe local reactions enforce it. Adherence to the diagnostic criteria of Jullien [(c 1886) i e, the triad purulent discharge, broad anal ulcer and condyloma], has been responsible for the failure to recognize the condition as a very small percentage of these patients present rhagades, external ulcers and condylomata."

MODE OF INFECTION

In women, gonorrheal proctitis ordinarily is secondary to genital infection. The vaginal discharge containing pus from the urethra, cervix or Bartholin's gland contaminates the anus. The normal eversion of the anus during defecation readily brings the pus in contact with the terminal rectal mucosa and infection follows. Contamination at defecation is the usual means of infection.

Other means of infection mentioned by various observers are the wearing of tight undergarments, contamination of the anus with infected urine, the partial expulsion and subsequent retraction of the final portion of a fecal mass, especially in constipated women, the backflow of a vaginal douche, contaminated rectal or vaginal syringes, rectal speculums or dilators, and rectal thermometers, the insertion of a suppository with infected fingers, rupture of a gonorrheal, prostatic abscess, peno-anal coitus, and rectal disease which brings the hands to the region of the anus.

MATERIAL STUDIED

One hundred and eleven women received treatment for genital gonorrhea. In these a positive rectal smear was obtained before the patients were examined proctoscopically. Smears were made from material obtained at the time of the proctoscopic examination as a check on the previous test. In some instances cultures were made.

INCIDENCE

Thirty per cent of the women affected with genital gonorrhea also had gonorrhea of the rectum. In 1927, 13 per cent of the women having gonococcic infection of the genitalia had symptoms of rectal involvement, in 1928 symptoms were present in 45 per cent. In 1929, when routine smears first were made from the anus and rectum, the diagnosis of gonorrheal proctitis increased immediately. It has varied since then from 25 to 42 per cent. Singer⁹ tabulates the published reports of a number of those investigators who observed the incidence of gonorrheal involvement of the rectum as shown in the accompanying table.

This investigator attributed the increase in 1922 and later "to the strong emphasis placed on routine examination for rectal gonorrhea." To digress at this point, I would mention that eight other authors report rectal infection as a complication of the vulvovaginitis of children in percentages ranging upward from 35, the incidence in Singer's own cases was 84.6 per cent. Thus, statistics show that rectal involvement is even more frequent in children than in women.

METHOD OF EXAMINATION

Smears were made from the rectum of every woman who exhibited an acute or a chronic gonococcic infection. A Kelly female urethroscope is inserted into the anus and through it a cotton-tipped applicator is passed into the rectum. Two smears are made from the mucus

Read before the Section on Gastro Enterology and Proctology at the Eighty-Fifth Annual Session of the American Medical Association, Cleveland, June 14, 1934.

or pus thus obtained, one slide is stained with methylene blue, the other by the Gram method. The finding of gram-negative, intracellular diplococci is accepted as evidence of gonococcal infection, gram-negative extracellular diplococci are not regarded as diagnostic. That among the rectal flora are other gram-negative diplococci, some of which may be intracellular, is well known, but that these often are confused with gonococci by an experienced bacteriologist who bases his opinion on the usual appearance, size and grouping of the gram-negative diplococci is unlikely. In our experience, cultural methods of isolation and identification have been inconclusive in too many instances to justify confidence in them. Smears containing gonococci generally were found to have 25 per cent or more of pus cells in them.

OTHER METHODS OF EXAMINATION

The Glingar method (rectal washing) is the injection of from 50 to 100 cc of tepid water into the rectum through a female catheter, the return flow is received into a narrow glass or tube and allowed to settle. Smears are made from the mucoid shreds or particles in the supernatant fluid. Temesváry¹⁰ and others obtain the specimen with a dull curet (Asch's). By some clinicians, Gauss's worm-shaped curet is used.

Singer thus summarizes his experience with the speculum-curet method and Glingar's "washing" procedure in 171 cases: "The Glingar method is most reliable but in the first examination fails in one third of the cases which are practically all diagnosed with the speculum-curet method. Inversely, nearly all cases negative with the speculum-curet method were proved positive by the Glingar method."

In my work, the simple cotton swab and endoscope method is thoroughly satisfactory, it causes the patient no discomfort. A single negative test does not rule out the infection.

SYMPTOMS

Usually symptoms are absent or manifestations of the infection are so slight that the physician's attention is not directed to the anus. In one series of eighty-eight cases which was investigated in 1931 only twelve (14 per cent) presented any rectal complaint, and 86 per cent were symptomless.

This year, among 111 patients examined with the proctoscope, thirty-six (32 per cent) on direct questioning stated that they had anal soreness, usually at bowel movement. Such soreness ordinarily was only moderate, although two patients were quite sore, six (54 per cent) had anal pain that was fairly severe, and three of these had anal fissures.

Bleeding, small in amount, usually just a streak on the paper or on the feces, occurred in thirty-two cases (28 per cent). Several patients noticed blood only two or three times. When internal hemorrhoids are present, blood commonly comes from these, this is especially true if the hemorrhoids become superficially ulcerated, as may occur with gonorrheal or any other type of infection. The bleeding usually is noted a few days after or accompanies the onset of the rectal infection. In a few instances it occurred from a few weeks to, in one case, three months later.

ONSET OF ANAL SYMPTOMS

In ten cases the patients stated that their rectal disturbances and gonorrhea started at the same time. That they actually did, however, is uncertain. The majority

noticed the rectal soreness or bleeding within three weeks of the onset of the genital infection, but there were a number who had no rectal trouble until after the first month, some subjects not until from two to seven months later.

From a summary of other of my data pertaining only to patients having symptoms of rectal involvement, it appears that rectal infection occurs within the first few days of the genital disease in about one third of the cases, in another third in the first three weeks, and in the remaining third at various times up to several months after the genital infection.

ANAL DISCHARGE

Pus or mucus occasionally may be seen by the physician on partial eversion of the anus by stretching the skin with the fingers, but it is not seen often enough to be of any diagnostic value. Even if present, it is not often noted by the patient because it is of small amount.

PHYSICAL MANIFESTATIONS

In a careful proctoscopic study of the 111 cases referred to there is no appearance of the rectal mucosa

Incidence of Gonorrheal Involvement

Author	Incidence
Almkvist	3.7% of cases of gonorrhea
Mattisohn	3.8% of cases of gonorrhea
Schener	5.0% of cases of gonorrhea
Buschke	8.0% of cases of gonorrhea
Mucha	10.8% of cases of gonorrhea
Harris	14.0% of cases of gonorrhea
Boas	16.0% of cases of gonorrhea
Huber	24.5% of cases of gonorrhea
Schmidt	27.7% of cases of gonorrhea
Levy Weissmann	25.35% of cases of gonorrhea
Eichhorn	30.6% of cases of gonorrhea
Baer	38.8% of cases of gonorrhea
Busche Klopstock	43.1% of cases of gonorrhea
Birger	41.3% of cases of gonorrhea
Gauss Schultz	75.3% of cases of gonorrhea

Singer's Own Records of Gonorrheal Proctitis

31.9%	1925
32.0%	1926
33.9%	1927

or anal canal characteristic of gonococcal infection. In 28 per cent of the cases, the terminal 6 to 10 cm of rectal mucosa was reddened, in 31 per cent of the cases it was doubtfully reddened and in the remaining 41 per cent the mucosal color was within normal limits. Thus, in well over two thirds of the cases one could not say that there was definite hyperemia of the mucosa. Other types of low proctitis involving the skin junction present similar appearances.

The anal skin at the mucocutaneous juncture was somewhat reddened or the small linear vessels in it were rather prominent in seventy-five of the 111 cases (67.5 per cent), in fifty-five slightly, in sixteen moderately, in one patient severely reddened. Hence in two thirds of our series there was some reddening of the skin margin. Mucopus, generally small in amount and often found as flecks or strings adherent to the wall, was noted in seventy (63 per cent) of the patients. Yellow liquid pus was seen in only six cases and was distributed diffusely over the last inch or last few inches of the rectum. I would emphasize this. The presence of mucopus in the last inch or two of the rectum is the most suggestive finding with respect to the diagnosis

¹⁰ Temesváry, Nikolaus. Rectal Gonorrhea in Women. Zentralbl f Gynak. 54: 3140 (Dec 13) 1930.

of gonococcic proctitis. It may be the only suggestion toward the diagnosis in a patient who states that she does not have gonorrhea or its symptoms. In the ordinary proctoscopic examination in which the patient is not a gonorrheal suspect, this finding demands the examination of a smear. In the gonorrhea suspect a smear for microscopic study is demanded.

DIAGNOSIS

Diagnosis is based on finding gram-negative intracellular diplococci in the smear made from material swabbed from the bowel wall and the upper part of the anal canal. A number of cultures were made on this last series (of 111 cases) and the procedure was repeated in some cases, but the results were unsatisfactory, as already stated. It is my opinion that a properly interpreted gram stain can be relied on.

COURSE

An early acute phase may occur, but that it is often absent is apparent. The course is slow and tedious, often several months, but cure may follow adequate care in from three to six weeks. Several weeks to months probably is the usual duration, as many patients discontinue treatment before being cured. Gonococcic infection, if untreated, will persist in the rectum a long time. I have found it a year after the initial genital infection. Reinfection definitely cannot be ruled out.

Gonorrheal proctitis is a potential source of genital reinfection. Temesvary states that this does occur, Bickel and Abraham state that it occurs only rarely. My own experience confirms that of the latter authors, who state that "the significance of rectal gonorrhea lies in its being a possible source of infection of the genitalia." In itself, rectal gonorrhea is usually not serious in the white races, in exceptional cases it may cause a stricture. In Negroes, inflammatory rectal stricture is more frequent, and this is regarded by many as an aftermath of rectal gonorrhea.

COMMENT

In women, especially, rectal gonorrhea is a more frequent complication of genital gonorrhea than is generally known. The chief reason why it is regarded as rare is that it is often overlooked. The conception that the infection usually causes a severe rectal inflammation is not true, anal ulcer, rhagades or condylomas are not common concomitants. Perhaps too many students and physicians have obtained their present notions of rectal gonorrhea from the free clinic or hospital dispensary, where Negroes are treated and where proctitis obliterans patients are seen and the probable relation of gonorrhea to the stricture has been stressed.

In 111 cases, three presented superficial fissures, perianal suppurative disease was found in three cases, two presented fistulas and one a short sinus communicating with an inflamed fibrosed crypt. In four patients the mucosa of the terminal rectum had a nodular surface, i. e., the early polypoid change that results from chronic mucosal infection. Superficial erosions, in small spots 1 to 2 mm in diameter, were observed on the mucosa just above its junction with the skin in four instances. No rectal or anal ulcers were encountered. Although a number of these cases were examined with the proctoscope very early in the course of their genital and rectal infections, the very severe cases described by some writers were not observed. Some of the women had much discomfort, especially at defecation, but not

many, and the anorectal inflammation was not uniformly proportionate to the complaint of the patients.

Stuhmer,¹¹ who accidentally conveyed the infection from one patient to twenty-five others by means of an infected glove, has described four phases of the disease. Only the last two usually are seen. In the first phase the mucosa is swollen and fiery red, the mucosal folds are obliterated, the lumen is quite filled with swollen mucosa, and the central orifice is square, irregular or arch shaped. The mucosa bleeds easily and on it there is greenish yellow mucus. The anus is reddened and very sore. In the second phase the swollen redundant mucosa recedes, the normally arched lumen reappears, the redness lessens, seedlike swellings, the color of the adjacent mucosa, are seen, the pus becomes thicker and does not adhere to the wall, and inflammation still is present in the anus. The third phase appears after one or two days, this is the proctoscopic picture commonly seen. There is considerable swelling and redness of the mucosa, the seeded appearance still is generally present, and thread-like pus is noted, which is quite adherent to the bowel wall. The fourth phase is characterized by the persistence of pus on the normal mucosa.

Stuhmer's experience is quite different from that in my series. This may be accounted for in part by the fact that he watched the tissue changes right from their inception. He may have been concerned with a more than ordinarily virulent strain of gonococci, which he transferred. Then, too, the lesions observed by Stuhmer were in men, two of the most severe cases that I have seen were in men, but I am not prepared to state that gonococci cause a more severe type of inflammation in the male than in the female rectum.

TREATMENT

Various procedures have been recommended for the management of the acute stage, for example, rest in bed, a bland diet, hot sitz baths, anal douches, local medication, and the avoidance of instrumentation. However, the disease is not often seen in this stage.

The patients in my series were treated by rectal instillations of 1 ounce (30 cc.) of 5 per cent mild silver protein twice daily. If anal soreness was prominent, an ointment or suppository containing a local anesthetic was employed. The bowels were regulated. The patients were instructed to instill the mild silver protein through an 18 or 20 French soft rubber catheter. No instances were seen in which the catheter traumatized the tissues. Objections to the use of the catheter appear unfounded, it is a practical method of having the patient receive medication at proper intervals. Hayes advocates a blunt-tipped bulb syringe to inject mild silver protein or similar medication. Smears were prepared from the rectal mucosa once a week in order to determine the results of medication.

The patients having fistula in ano were operated on when the disease was chronic but while smears were still positive. The wounds healed normally.

CONCLUSIONS

1. Gonococcic infection of the rectum is a common complication of the genital infection in women.
2. Because symptoms usually are mild and often absent, frequently the lesion is not diagnosed.
3. Routine rectal smears should be made of all women who exhibit a gonococcic infection of the urethra or the

¹¹ Stuhmer, A. The Clinical Course of Rectal Gonorrhea. *Dermat. Ztschr.* 32:12, 1921.

cervix. Such routine examination is of value in any gynecologic or urologic service.

4 Although rectal gonorrhea usually is not serious in itself it is of some importance as a possible source of reinfection. Because it persists in the rectum after the genital tract is clear, the rectum must be considered as a source of reinfection when all other possibilities have been excluded.

55 East Washington Street

ABSTRACT OF DISCUSSION

DR. HERBERT T. HAYS, Houston, Texas. Many cases of rectal gonorrhea are not found unless they are looked for, and in white women especially they may be asymptomatic. Dr. Martin reports the occurrence of gonorrheal proctitis following genital gonorrhea in women in from 25 to 42 per cent, but in my experience it has been slightly higher. The diagnosis is easily made in early cases, but in the chronic cases, which are often associated with complications such as stricture and fistula, repeated smears are necessary to discover the organisms. Dr. Martin suggests the use of 5 per cent mild silver protein in gelatin twice daily instilled with a catheter. I usually use the mildest silver solution possible and instill it with a blunt-tipped syringe placed against the anus forcing the liquid in by pressing on the bulb. I have thought this more advisable in the early cases than inserting any instruments into the rectum, as I believe any trauma to this already inflamed mucosa is likely to cause trouble. In the more advanced cases, however, I do not think there is any contraindication to the insertion of a catheter and irrigating the rectum. Gonorrheal proctitis is often very persistent, but this is the case when there are certain types of lesions which harbor the infection. Most important of these are stricture of the rectum, fistula-in-ano, hemorrhoids, cryptitis, prolapse and fissure. It seems especially hard for these cases to immunize themselves, and it is best to operate on these complicating factors and eliminate them if possible. I have had to do this in a number of chronic cases and the wound healed satisfactorily but required rigid after-care. In most instances gonorrheal proctitis in white women will clear up without any complications. If complications do arise, they can be eradicated and cured except in the few cases in which a stricture develops. However, in Negro women there is quite a different history. Treatment is exceedingly unsatisfactory and many develop a rectal stricture, the infection persists for years, and they are more or less permanently incapacitated.

DR. CURTICE ROSSER, Dallas, Texas. Dr. Martin's description of the course, symptoms and complications in his cases confirm in many details my observations in a much smaller group reported before this section in 1933. Reddening not ulceration of the mucosa, of the upper anal canal and of the skin of the lower anal canal and mucopus, occasionally yellow, were the two variations from normal most commonly seen through the proctoscope. Dr. Martin makes no mention of the role the anal crypt plays in "anal gonorrhea." I must continue to urge the use of this term as more accurate and descriptive than "rectal gonorrhea" for a condition in which the major lesions, the crypts in which the organisms secrete themselves in the chronic stage and the complications are all in and about the anal canal not in the ampulla of the rectum. My conviction that the anal crypts serve as reservoirs of infection in anal gonorrhea was first expressed before this section eight years ago. In 1933 I emphasized this contention by reporting cases in which crypt infection was directly observed. Such complications as abscess, fistula, erosions and granulations of the mucosa above and adjacent to the dentate line are best explained by the presence of a chronic infection in the anal crypts, hidden foci analogous to the urethral glands and prostate in gonorrhea of the conventional type. The work of Tucker and Hellwig reported this year is further confirmation of the fact that the gonococcus embeds itself in and about the crypts of Morgagni. While Dr. Martin like other writers, has almost studiously avoided mention of the anal crypts the lesions he relates serve as confirmatory evidence of their importance in the disease. The author called atten-

tion to the fact that chronic gonorrheal infection may persist long after all symptoms subside and be a potential source of reinfection. Vigorous treatment directed to the anal crypts in the chronic stage is the logical answer to these facts.

DR. CLAUDE C. TUCKER, Wichita, Kan. At the City and County Clinic for the past year I have asked that all persons with a positive vaginal finding of gonococci be sent to my clinic for proctoscopic examination. Many had no symptoms, but a big percentage showed positive smears with duct and crypt infection. The anal ducts are the foci of infection, the anus being constantly bathed in pus, especially at the time of defecation. The gonococci enter the ducts through the crypts of Morgagni. Gonorrheal infections in the anal ducts, peri-urethral and prostate, give the same microscopic picture. Embryologic studies have shown that the anal ducts, the para-urethral ducts in the female, and the prostate gland in the male develop from the same structures, namely, the embryologic cloaca. Anal ducts play apparently the same role in gonococcal reinfection as do the prostatic and para-urethral ducts.

DR. CLEMENT L. MARTIN, Chicago. One of the chief reasons for presenting this paper was to record the usual clinical and proctoscopic picture of rectal gonorrhea. I wish to avoid distortion of this picture by overemphasis of crypt and duct infection. The data in this series speak for themselves. I am following the work of Tucker and Hellwig with much interest. The anal duct phase was purposely omitted. That the anal ducts constitute an important factor in the persistence of rectal infection is a logical assumption. That such ducts exist is proved, but that they are always or even generally present has not been sufficiently demonstrated. That they are normally present is certainly possible and I hope that the work of Tucker and Hellwig and those who are trying to verify their observations will settle the point. The small percentage of this series having demonstrable lesions resulting from duct or crypt infection suggests on its face my being conservative until further pathologic data from excised tissue are available.

SYMPTOMS IN EARLY STAGES OF INDUSTRIAL PLUMBISM

ROY R. JONES, MD

Passed Assistant Surgeon, United States Public Health Service

WASHINGTON, D. C.

[EDITORIAL NOTE.—This paper together with the papers of Drs. Gray and Belknap which follow it concludes the symposium on lead poisoning. In the last issue were published the papers of Lanza of Aub and of Kehoe, Thammann and Cholak.]

My purpose in this paper is to review briefly, from the point of view of the industrial physician, the various signs and symptoms commonly associated with plumbism and to discuss more fully some of those observations which may usually be considered of the greatest value in its early diagnosis. It is obvious to those acquainted with this problem in industry that efforts to reduce the incidence of industrial plumbism will be greatly handicapped if emphasis is not placed on such observations as may be considered presumptive evidence of lead absorption or lead intoxication.

From an early date medical literature has been replete with reports dealing with the toxic effects of lead. With few exceptions the signs and symptoms considered in the present discussion have been fully described by early medical workers. Later scientists are to be given credit for experimental studies made to determine the action of lead on the body tissues, and definite contributions have been made by those groups studying hygienic conditions in industry and their relation to the health of the men employed.

Read before the Section on Preventive and Industrial Medicine and Public Health at the Eighty-Fifth Annual Session of the American Medical Association, Cleveland, June 13, 1934.

Many conditions may influence the reaction of the tissues to lead. Such personal factors as past and present illnesses, age, hygienic habits and constitutional development, and such physical factors as type and amount of lead absorbed, its rate of absorption or solubility in the body fluids, and the like, all affect the body's response to this metal.

A complete record of all the signs and symptoms that have been reported to be associated with plumbism would of necessity contain most of those common to all body ailments. This discussion is purposely limited to those signs or symptoms which are most frequently exhibited. Although no single sign or symptom may be considered pathognomonic of plumbism, certain interest may be attached to the characteristic grouping of these symptoms and the period in the course of the disease when they are usually manifested.

The present remarks are based on a review of the literature and on observations made on men employed in the storage battery industry.¹ In all, about 1,500 storage battery employees were observed during a period of nearly two years, from June 1928 to February 1930. These workers may be considered in two classes (A), a group suspected of plumbism reporting to the clinic for examination, and (B), a group actually on compensation for lead poisoning.

For convenience the common symptoms are considered in groups referable to the system involved. By a further classification of them within groups according to the period in the course of the disease when they are usually manifested, it is possible to offer a summary, which, in general, may serve as a basis for making a diagnosis of

- 1 Abnormal lead absorption
- 2 Incipient lead intoxication.
- 3 Definite lead poisoning

It must be borne in mind, however, that proper and valid interpretation of such signs is arrived at only after due consideration of other facts elicited through the taking of a complete occupational and past medical history.

COMMON SIGNS AND SYMPTOMS

General Appearance—Although it is possible for plumbism to develop without producing much, if any, change in the general appearance of an individual, close observation of persons possibly exposed to a lead hazard will often reveal suggestive evidence of abnormal lead absorption. Some of those changes most frequently observed are shown in table 1A. The most common may be the development of a lead line at the margin of the gums, about which much has been said. Its presence is indicative of the absorption of lead at some time. The same, however, might be due to the absorption of lead at so slow a rate as would not necessarily cause disability. Furthermore, it is often more pronounced in those cases in which mouth infections have been neglected. Less than half of the battery workers suffering from plumbism showed this sign. That it cannot be relied on as early evidence of lead intoxication is shown by the fact that many severely poisoned persons do not show any trace of a lead line, while others with no definite evidence of intoxication may exhibit marked lead lines.

One of the most significant, so far as indicating that the absorption is recent, is a perceptible change in the individual's disposition. Such persons are prone to be easily flustered and may appear moody. Because of such changes, men were sometimes ordered to the clinic for examination by their foreman.

Early suggestive evidence of incipient lead poisoning, aside from the lead line, is sometimes indicated by the sclera becoming slightly jaundiced. Aub and his co-workers² state that pallor is the most constant sign

TABLE 1—Common Signs and Symptoms Observed in Cases of Plumbism and Excessive Absorption of Lead

Suggestive Evidence of Lead Absorption	Suggestive Evidence of Incipient Intoxication	Suggestive Evidence of More Advanced or Definite Plumbism
	A General Appearance	
Restive, moody, easily excited, flustered	Pallor	Anemia
Lead line	Lead line	Lead line
	Jaundice	Jaundice
		Emaciation
		"Premature aging"
	B Digestive System	
Persistent metallic taste	Metallic taste	Metallic taste
Slight loss of appetite	Definite loss of appetite	Increased loss of appetite
Slight constipation	Coated tongue	Nausea and vomiting
	Slight abdominal colic	Coated tongue
	Constipation	Marked abdominal colic
		Rigid abdomen
		Marked constipation
		Blood in the stool
	C Nervous System	
Irritable	Slight headache	Increased headache
Uncooperative	Insomnia	Increased insomnia
	Slight dizziness	Increased dizziness (ataxia)
	Palpitation	Confusion
	Increased irritability	Marked reflex changes
	Increased reflexes	Tremor
		Fibrillary twitching
		Neuritis
		Visual disturbances
		Encephalitis (hallucinations, convulsions, coma)
		Paralysis
	D Miscellaneous Changes	
None	Muscle soreness	General weakness
	Easily fatigued	Joint pains
	Hypotension	Hypertension
	E Urine Examination	
Positive test for lead	Positive test for lead	Positive test for lead
	Trace of albumin	Increase in albumin and casts
	Few granular casts	Hematuria
		Hematuria present
		Hematuria
	F Blood Changes	
Polycythemia	Normal red blood cell count and normal hemoglobin	Decrease in hemoglobin
Polychromatophyllia	Further increase in reticulocytes	Decrease in total number of red blood cells
Increased platelets	From 50 to 100 stippled cells per hundred thousand erythrocytes	Increase in all forms of nucleophilic cells
Percentage of reticulocytes about doubled		Increase in percentage of mononuclears
		Anisocytosis and poikilocytosis
		Nucleated red cells present in the peripheral circulation
		Decreased platelets

of early intoxication. In the group of battery workers, considered as a class, showing signs of incipient lead poisoning, jaundice was more often recorded than was pallor, but in the group on which a definite diagnosis of lead poisoning was made pallor was found as frequently as any early change in general appearance.

The most common subacute and chronic forms of plumbism, in addition to the symptoms noted earlier, are usually accompanied by certain changes in the physical appearance, best described by the term "premature aging." These patients are characterized by their list

¹ Russell, A. E., Jones, R. R., Bloomfield, J. J., Britten, R. H., and Thompson, L. R. *Lead Poisoning in a Storage Battery Plant*. Pub. Health Bull. 205, 1933.

² Aub, J. C., Fairhall, L. T., Minot, Anne S., and Reznikoff, Paul. *Lead Poisoning*. Medicine Monographs, Baltimore, Williams and Wilkins Company, 7, 1926.

less attitude, stooping posture, apparent loss of weight, strength and muscle tone, and general anemic condition. This premature aging and wasting may persist long after removal from exposure.

Digestive System—Some observers believe that the signs and symptoms referable to the digestive system are those most frequently found to be the earliest evidence of lead absorption and intoxication. In table 1 B are given those signs which will probably be most commonly exhibited because of changes in the normal digestive processes, arranged according to the period in the course of the disease when they are most likely to occur.

In our group of workers suspected of plumbism, such signs as a persistent metallic taste, slight loss of appetite for the morning meal, and a tendency to constipation were sometimes complained of when no other cause for their presence was elicited than that the patients might be absorbing abnormal amounts of lead. An increase in these symptoms and further evidence, such as a foul breath and coated tongue and slight abdominal colic, was noted in those cases proved to be incipient lead poisoning. All these signs were exaggerated in the moderate or advanced cases. The colic associated with plumbism is usually quite marked. It was complained of in more than 90 per cent of the battery workers in whom definite cases developed and by all those affected sufficiently to be entitled to compensation. Not only was the colic more severe in the advanced cases but also, during an attack, the abdomen would become very rigid. Another feature of this colic associated with plumbism is that the pain is somewhat lessened by pressure on the abdomen. The patient is prone to hold the hands firmly over the abdomen during an attack of colic or, if he is able to be up and about, will stop and bend over the back of a chair or some other object, since firm and continued pressure will usually bring some measure of relief. In some patients, obstipation develops which necessitates drastic measures to overcome it. Marked loss of appetite, nausea and vomiting were common. Occasionally, following severe colic, blood may be found in the stool.

Nervous System—The signs and symptoms referable to the nervous system are of special importance in the detection of early evidence of abnormal lead absorption. In table 1 C the signs and symptoms associated with nervous changes resulting from lead absorption are shown, classed in groups denoting the time when they were most often evident.

The group of workers suspected of lead poisoning all showed mild signs of increasing irritability and nervousness, usually before they offered any complaints. The group that proved to be suffering from plumbism invariably gave a history of such nervous symptoms having antedated the more severe manifestations of lead poisoning. They often remembered that they had been subject to slight headaches, which tended to clear up after they had been at work for a few hours. This, at that time, they were prone to account for by the fact that they had not slept so well or that the bowels were slightly constipated. Of course, loss of sleep and worry from any number of causes may produce like symptoms, but careful questioning will in most cases enable the examiner to judge whether there are other reasons to account for such nervous symptoms. Failing any other explanation for the exhibition of these early nervous signs by persons with a known or suspected exposure to lead, one may advantageously accept this

as presumptive evidence of abnormal lead absorption or incipient intoxication. The tremor and fibrillary twitching appearing somewhat later are comparable to that associated with alcoholism. It is more noticeable when stimulated by external irritation or fatigue. This fine fibrillary twitching was most often observed in the muscles of the face and upper extremities and was more pronounced when the person was tired. The workers presenting objective nervous signs often complained of dizziness and headache and seemed to have lost interest in their work. Occasionally, one of the earliest complaints was palpitation, more noticeable after the day's work. In my experience visual disturbances were seldom mentioned, even by those off duty because of plumbism. Wrist drop, so often reported as resulting from lead poisoning, was not observed among the group of storage battery workers, nor was there any record of the condition developing among previous employees at that plant. Reflex changes were noted in more than 70 per cent of the cases of definite plumbism. These changes are of particular interest when those examined are considered in two groups. One group, suffering from their first attack, showed increased reflex action. This increase was quite marked, especially in those cases of poisoning showing marked irritability, rigid abdomen and rapid development. On the contrary, those suffering from relapses or repeated attacks, in whom the condition had progressed to a more chronic stage, commonly showed an appreciable decrease in reflex action.

Some of the nervous signs indicating cerebral involvement, such as the development of delirium, hallucinations, maniacal tendencies, convulsions and coma, were not observed among the storage battery employees. One case was observed in which the initial diagnosis was encephalitis, however, this case was not fatal and occurred in a man who was afterward discovered to have been previously an inmate of the state insane asylum.

Miscellaneous—Those changes chiefly associated with general nutrition and muscular development, but also closely related to the neurocirculatory systems, are listed in table 1 D.

Early in cases of definite plumbism the individual will often complain that he tires easily and is aware of a vague muscle soreness, the latter affecting usually the muscles of the back and thigh. Some of the cases, possibly too few to be of statistical significance, were found in the early stages to exhibit a slight hypotension. Weakness was not an early symptom. When complained of early in the development of plumbism, it could be in part at least attributed to a lack of nourishment and rest resulting from loss of sleep and dietary restrictions. In more advanced and usually more chronic cases there is a frequent complaint of definite loss of strength and weight and a constant tired feeling even after a prolonged rest. Joint pains are particularly likely to be chronic and are often difficult to interpret satisfactorily. Hypertension, which has sometimes been reported as associated with chronic plumbism, was not shown to be more frequent among the group of battery workers than it has been shown to occur among other workers of similar ages. This may be explained by giving consideration to the relative rapidity with which many of the cases developed.

LABORATORY OBSERVATIONS

Aside from the signs and symptoms observed by questioning and by examining workers suspected of

absorbing abnormal amounts of lead, all agree that certain facts to be learned from laboratory examination of the blood and urine are almost indispensable. Some of the more common changes that may be looked for in making an examination of the urine excreted by persons who may be exposed to a lead hazard are given in table 1 E.

By spectroscopic examination of the blood and other body fluids it has been proved possible to demonstrate definite evidence of lead intake, however, such procedures are not always adaptable to routine use by the average physician. In recent years a roentgen examination of the bones also has been shown to be an aid in detecting evidence of lead absorption.

Examination of Urine—The presence of albumin and granular casts in urine excreted by persons previously well, when accompanied by other evidence of lead intoxication, may serve to indicate somewhat the degree of lead poisoning. No one will question the finding of abnormal amounts of lead in the urine as evidence of absorption. Some discussion and disagreement have accompanied the efforts of workers to establish what may be accepted as the maximum amount of lead that may be found in urine excreted by persons normally. Badham³ believes that the presence of more than 0.05 mg. of lead per liter of urine is evidence of mild lead poisoning if accompanied by other evidences of the disease. Kehoe and his associates⁴ report finding as much as 0.08 mg. of lead per liter of urine excreted by normal persons with no known exposure to lead. Aub² is of the opinion that too much weight should not be placed on the presence or absence of lead in the excreta, owing to the fact that during exposure lead is not always excreted and that its presence does not always mean intoxication. Under certain conditions, excessive lead found in the urine of persons with a known or suspected exposure to lead, who on previous examination were not found to excrete abnormal amounts, would indicate recent absorption possibly earlier than other changes. Nevertheless, from the point of view of the average physician, owing to the equipment, training and time required for making such chemical examination, this method of detecting early absorption of lead is not so practical as other laboratory procedures.

Some writers report the finding of hematoporphyrin in the urine as one positive evidence of lead poisoning. I found this to be so in but a small percentage of cases, and others report that it is not a constant finding.

Blood Changes—Many of the restrictions applicable to the acceptance of lead in the urine as an early sign of lead absorption hold also for positive blood changes. Microscopic examination of the blood, however, is much more practical, and when observations so obtained are considered in the light of knowledge gained by the history and the physical examination, they furnish information of real value in making a diagnosis. Some of the more common changes in the blood picture to be looked for in various degrees of lead absorption are given in table 1 F.

Various degrees of anemia are shown by patients suffering from chronic lead poisoning, but this has not

been proved to be an early sign of the effects of lead absorption. The changes in the morphology of the red blood cells parallel the decrease in total number and the decrease in the amount of hemoglobin. In about 5 per cent of the cases of chronic plumbism this anemia had progressed to the point at which nucleated red blood cells were found in the peripheral circulation.

Another point of interest, concerning which little mention has been made, is the fact that some of the more advanced cases of plumbism will show a decrease in the number of blood platelets. Some of the early cases, on the other hand, will show an increase in platelets at the time when a definite condition of polycythemia is present. In a group of forty-two cases of moderately severe plumbism, I found an average platelet count of 130,000 per cubic millimeter, as compared with similar counts made on controls, which ranged from 250,000 to 700,000. No case presenting a decrease in platelets showed any special tendency to hemorrhage.

The reduction of platelets in chronic cases may be explained by the other changes in the blood picture and alterations present in the bone marrow. Aub and his associates² report that the irritating effect of lead on the bone marrow ultimately produces a definite change, resulting in a decreased output of normal blood cells, the release of immature red cells and a relative increase in the number of mononuclear leukocytes.

Because considerable change must take place in the bone marrow before a reduction in the number of platelets is manifested, the finding of such a decrease is of no value in the detection of early lead poisoning. This finding assumes particular significance in determining the extent of bone marrow injury and the inadvisability of permitting persons presenting this sign to be subjected to further exposure.

In the group examined who were on compensation for plumbism, a relative increase of a slight degree in the number of mononuclear cells was found more often than was a decrease in platelets. However, neither of these changes was noted in those cases showing the earliest and minor signs of lead absorption or incipient intoxication.

There is one blood change that is generally considered of extreme importance as a sign of lead absorption and is very practical in its application. The cases of plumbism that show no increase in the number of basophilic cells are usually of such long standing and so far advanced that no trouble is experienced in making a definite diagnosis. While the phenomenon of stippling has never been fully explained, the presence of stippled cells in blood films made from persons suffering from plumbism has been given more consideration than any other one finding. It is true that stippled cells will be found in the blood of persons suffering from other conditions associated with various degrees of anemia, but in no other disease are stippled cells found in such numbers in the absence of other major blood changes. In cases of acute lead poisoning it is possible that their presence will be one of the earliest signs of lead absorption but since most industrial lead poisoning is of a chronic form there are other signs that will be present as evidence of basophilia before the appearance of the stippled cell.

As mentioned previously, often the early effect of lead on the marrow is of such a nature that instead of a decrease in the total number of erythrocytes there is

³ Badham, C. Lead Poisoning. Studies in Industrial Hygiene No. 7, report of the Director General of Public Health, New South Wales for the year ended Dec. 31, 1925.

⁴ Kehoe, R. A., Thammann, Frederick, and Cholak, Jacob. On the Normal Absorption and Excretion of Lead. II. Lead Absorption and Lead Excretion on Modern American Life. *J. Indust. Hyg.* 15: 273 (Sept.) 1933.

actually a condition of polycythemia Alice Hamilton⁵ states that the stippled cells are really degenerated reticulocytes. Whether these cells are degenerative forms may not be proved conclusively, but in recent years, particularly, sufficient evidence has been produced to prove that they are the juvenile red blood cell. The work of Key⁶ and earlier works of Askanazy,⁷ Biondi,⁸ Hawes,⁹ Robertson¹⁰ and others give satisfactory evidence that stippled cells are but one manifestation of polychromatophilia. The work of Schwarz,¹¹ Seiffert¹² and McCord¹³ is based on this principle. Certainly if the basophilic cells or reticulocytes are the ones eventually to become stippled, owing to the action of lead, an early increase in such cells is to be expected before stippling to any great extent will become manifest. Therefore the particular method of examining the blood for the smallest increase in these new cells should furnish the earliest evidence of any irritating or toxic action of lead, especially in those persons recently exposed for the first time who previously have shown no increase in percentage of reticulocytes. McCord's method of estimating the increase in basophilia is a distinct improvement over that of counting only the stippled cells from a fixed preparation. Owing, however, to the fact that by his technic it is not possible to measure this increase when it is slight, some of its advantage is lost. Any standard method of estimating an increase in reticulocytes should give positive evidence before that obtained by a thick drop method. In the work reported here a slightly different basic staining technic was used than the techniques described by Schwarz,¹¹ Seiffert¹² or McCord¹³. However, in principle they were all based on the method proposed by Ehrlich¹⁴ for staining the basophilic substance in the erythrocyte. By using thin films and fixing but half of the film through its long dimension, not only was I able to estimate the number of cells in which a given number of reticulocytes were found but also the fixed portion furnished a preparation from which the number of stippled cells per million erythrocytes could be estimated. Further study of this method proved that the reticulocyte counts obtained by such a technic were the same as those obtained when vital staining methods were used.¹⁵ Probably one of the clearest demonstrations of the relationship between the diffuse polychromatic cell, the punctate basophilic cell and the reticulocyte is given by the report of Whitby and Britton¹⁶. A summary of this report states that "polychromasia and stippling are both manifestations of the

phenomenon of reticulation. The polychromatic cells of Leishman stained films and the reticulocyte of supravital stained films are identical and normal. Stippling is the same chromatic substance slightly altered by lead or other poison. The alteration appears to have no effect on the efficiency or life of the cell."

In the present study a parallel increase in reticulocytes was found with the increase of stippled cells, but this increase in reticulocytes was always manifested prior to the finding of a significant number of stippled cells. In more advanced cases the reticulocyte count was always much greater than that of stippled cells. Cases were examined that showed stippled cell counts as low as 6 per hundred thousand erythrocytes, and reticulocyte estimations made on these individuals at the same time showed from two to three times as many as are normally present. To determine the stippled counts when they occur in such small numbers requires from two to three hours, while the accompanying increase in reticulocytes may be determined in a few minutes. Table 2 shows the correlation of the stippled cell and the reticulocyte count and the marked increase in the number of reticulocytes to be found early in the course of lead absorption.

TABLE 2—Correlation of Stippled Cell and Reticulocyte Count

Stippled Cells per 100 000 Red Blood Cells	Ratio of Number of Reticulocytes Found in Workers Suspected of Plumbism to the Number Found in Nonexposed (Applicants)
Applicants	
None	1 00
Workers showing	
Less than 6	2.00
6 to 9	3.31
10 to 12	4.18
13 to 15	5.34
16 to 39	8.78
40 to 99	18.73
1,000 to 1,500	22.71
1,600 to 2,400	27.60
2,500 to 3,000	33.61

I saw men removed from exposure, or whose working environment was improved because this early change was manifested, in whom disabling plumbism did not develop, while in others who were left until greater increases were noted, plumbism developed to the extent that they lost time from work, and some actually were placed on compensation for lead poisoning. Aub² reports reticulocyte counts of from 6 to 16 per cent in two lead colic patients with erythrocyte counts of approximately $3\frac{1}{2}$ million. Fleckel and Tschernow¹⁷ reported a method of classifying the degree of lead absorption in individuals by the percentage of their red blood cells showing reticulations. Bottrich¹⁸ also reports on the usefulness of this finding in cases of plumbism. I. M. Fleckel¹⁹ reports the value of reticulocyte estimation in diagnosis in cases of chronic lead enterocolitis. It must be remembered, however, that the presence of an increase in reticulocytes is due to the same cause that later leads to the presence of abnormal numbers of stippled cells in the blood, and therefore records of counts made before exposure and at intervals during exposure are of importance in judging the change produced.

DIAGNOSTIC STANDARDS

The Committee on Lead Poisoning of the American Public Health Association²⁰ has given an excellent discussion on the subject of standards of diagnosis based particularly on the degree of disability indicated by certain groups of signs. It realized that much of the confusion existing in the ranks of the medical profession regarding the diagnosis of plumbism, its degree and the amount of disability, was due to the lack of uniformity in terminology used to express opinions. Its report contains a classification of terms used and it supplies definitions applicable to their use. This report properly emphasizes the necessity of obtaining complete occupational and medical histories and the consideration of all such information as may be gained from them along with the results obtained from careful physical examination and laboratory studies.

Newman, McConnell, Spencer and Phillips²¹ devised such a standard for use in the particular study that they were carrying on among a group of pottery workers. This standard as applied to their work aided greatly in the making of an orderly analysis of their records, and some such method is often quite necessary in the making of a statistical analysis of observations from a group. However, if such standards were closely relied on in the individual case as seen by the physician, some errors in diagnosis would certainly follow.

Often one finds references to such standards as proposed by Badham³ and others, which have been suggested to be of value when necessary to express the stage or severity of initial attacks of lead poisoning.

Aub and his associates² in their monograph on lead poisoning offer helpful criticism regarding the value of such standards. In brief, it is their opinion that these standards place too much significance on a single symptom, regardless of the degree of change indicated by it. They state that in the last analysis the diagnosis of plumbism must depend on keen judgment and that no fast rules can be adopted.

For the purpose of classifying the degree of disability associated with an attack of plumbism, it may seem advantageous to outline some group of symptoms that may usually be assumed as indicative of the severity of the attack, but, as an aid in making a diagnosis before definite intoxication, these standards are less practical. In each instance, all factors must be considered and the same procedure followed in arriving at a diagnosis as is necessary in other disease presenting constitutional reactions that are so varied and extensive.

SUMMARY

In dealing with the problem of industrial plumbism, emphasis should be placed on those signs and symptoms commonly exhibited early in the course of absorption or intoxication. All observations should be considered in their relation to the entire clinical picture in order to arrive at a diagnosis, especially in the preintoxicative stage. All changes listed as presumptive evidence should be thoroughly investigated. From a practical point of view it is believed that, by careful watching for an early reticulocyte response, the physician will be able to detect evidence of lead absorption prior to the development of definite plumbism.

²⁰ Report of the Committee on Lead Poisoning, American Public Health Association, presented before the Industrial Hygiene Section at the annual meeting in October 1929.

RECENT PROGRESS IN THE TREATMENT OF PLUMBISM

IRVING GRAY, MD

BROOKLYN

The opportunity for studying a group of patients with lead poisoning was afforded because of the contentious situation that arose in the adjudication of their disability. In one group of individuals a diagnosis of chronic lead poisoning had been made from six months to two years prior to coming under my observation. The problem that arose was to determine whether or not protracted subjective symptoms were due to chronic lead poisoning and, if so, to institute a method of treatment. There were nine patients in this group.

In a second group, more recently exposed to either the ingestion or the inhalation of lead, a diagnosis of subacute lead poisoning had been made. The problem here was to determine the best type of treatment to bring about recovery. There were four patients in this group.

In a third group (two patients) it was alleged that subjective symptoms of recent origin were due to contact with lead over a period of many years. The problem was to determine whether or not lead was a causative factor in the production of symptoms.

LITERATURE

Recent progress in the treatment of lead poisoning has been due largely to the studies of American investigators. A knowledge of conditions hindering or favoring the liberation of lead is naturally of importance. In 1926 Aub, Fairhall, Minot and Reznikoff¹ published their observations on the excretion of lead following an exhaustive investigation on lead metabolism in man and in cats. They found that lead could be either stored or excreted by distorting the calcium metabolism. A negative calcium balance increases the rate of lead excretion, while a positive calcium balance favors the storage of lead. The rate of lead excretion can further be increased by the addition of ammonium chloride or phosphoric acid. "Deleading" treatment is to be recommended only when acute active symptoms are not present. In further studies Aub and Hunter² show that the parathyroid hormone increases the rate of lead excretion in patients suffering from lead poisoning.

Recently, Kehoe, Thamann and Cholak³ have made careful and intensive studies on the normal absorption and excretion of lead. Their studies on the behavior of lead in the human organism are important contributions to knowledge. Kehoe has advised against the administration of agents which are believed known to promote a quick release of lead from the tissues. He and his co-workers call attention to the danger of "deleading" rapidly and the possible storage of this mobilized lead in the central nervous system.

In 1932 Shelling⁴ studied the effect of dietary calcium and phosphorus on the toxicity of lead in the animal. He states that the deposition of calcium phosphate in the course of normal ossification, or the deposition of other insoluble phosphates such as lead, can occur only when the phosphorus intake is adequate for the deposition and for the excretion of the excess cations as the insoluble salts in the feces. On theoretical grounds, he believes, it would seem logical that if the aim in the treatment of lead poisoning is to deposit or excrete the lead in an insoluble or innocuous form, such as the phosphate, an abundance of phosphorus or foods containing phosphorus should be supplied. In his experimental work on rats he showed that the introduction of large amounts of calcium without phosphorus diverts the available phosphorus to rid the body of the excess calcium as the phosphate and thus interferes with the formation of such a compound with lead. Shelling injected colloidal lead phosphate into rabbits and fed them diets very high in calcium or high in phosphorus and the results were in accord with his previous observations, i. e., that the high calcium diets are more toxic than the diets high in phosphorus. As the result of his experimental work, Shelling believes that phosphorus is important in depositing lead in the bones and also in "deleading." "Deleading" may be accomplished by giving a diet low in calcium and relatively high in phosphorus, so that the cations removed from the bones are excreted as the insoluble phosphates. It has also been shown by Bischoff⁵ and his co-workers that lead added to serum is less toxic than ordinary lead and that colloidal lead phosphate possesses the same degree of toxicity as lead in serum. Apparently the addition of lead to serum forms a colloidal lead phosphate, which is not as toxic as any other form of lead. The addition of phosphate to the diet and subsequent increase of phosphate in the blood may produce this lead phosphate combination *in vivo*.

That disturbances of metabolism play an important part in the liberation of lead stored in the system was suggested by Shie,⁶ but as early as 1861 Gussierow⁷ made the statement that the desirable condition of having lead permanently stored in the bones probably does not exist.

DIETS EMPLOYED (LOW CALCIUM, HIGH PHOSPHORUS)

In some of the cases treated early, the low calcium diet as recommended by Aub and his associates¹ was used, which consists of meat, liver, potato, rice, tomatoes (cooked without milk), canned corn, bananas, apples (peeled), tea, coffee (without milk), butter fat, bread (prepared without milk, such as salt-free nephritic bread or sodium bicarbonate biscuits or crackers), sugar, salt, pepper. In addition, at varying intervals, the patients were given phosphoric acid and ammonium chloride. Catharsis by the use of magnesium sulphate was continued during treatment. Following the report by Shelling⁴ of his experimental work a diet

was arranged so as to have a low calcium-high phosphorus content, with the ratio 1-3 or 1-4. The vitamin and caloric content is sufficient for daily need. Vitamin D, however, was deficient in the diet and 20 minims of viosterol (250 D) daily was added.

CASES ILLUSTRATIVE OF "DELEADING" IN CHRONIC PLUMBISM

These patients had been exposed to lead absorption over a period of years. Symptoms had been present in this group from six months to two years and had arisen during the period when it was reasonable to assume that lead was being absorbed. A diagnosis of chronic lead poisoning had been made in these individuals and compensation was awarded on the basis of their occupational disease.

The physical examination in all these individuals failed to show any objective evidences indicative of plumbism.

A modification of the method described by Fairhall⁸ was used in examining the excreta for lead. All cases were treated and studied under hospital supervision.

CASE 1—History—S. P., a man, aged 34, had been employed as a painter for thirteen years. In December 1931 he began to complain of abdominal cramps, occasional vomiting and increasing constipation. A diagnosis of lead poisoning was made. He stopped working and has had no exposure to lead since. He came under my observation early in 1933 complaining of weakness, poor appetite, occasional vomiting and constipation.

Examination—On physical examination he was well developed. Examination was essentially negative. The blood pressure was 126 systolic, 78 diastolic.

In the control series there was no lead present in 1,200 cc. of urine (twenty-four hour specimen) or in 30 Gm of stool.

The blood showed red blood cells, 4,350,000, hemoglobin, 86 per cent, platelets, 180,000. The red blood cells were normal in appearance, with no stippling.

Treatment and Results—The "deleading" treatment consisted of the low calcium diet of Aub and his co-workers, and phosphoric acid, 10 cc., once every hour, for ten doses daily, and magnesium sulphate, one-half ounce (15 Gm) every morning.

Forty-eight hours after treatment was instituted, daily twenty-four hour specimens of urine showed an average of from 14 to 26 mg of lead. At the end of two weeks a trace of lead too small in amount to estimate was obtained. At the end of three weeks lead could not be detected in the urine.

Amounts varying from 15 to 32 mg of lead were found in 50 Gm of stool. These examinations were made at intervals of forty eight hours.

Blood chemistry showed normal results: carbon dioxide, 59.4 volumes per cent, calcium, 101 mg per hundred cubic centimeters, phosphorus, 50 mg per hundred cubic centimeters. Repeated blood smear studies showed no stippling of the red blood cells.

Two subsequent examinations after discharge from the hospital showed no lead in the urine.

CASE 2—History—T. H., a man, aged 56, had been employed as a plumber for the past fifteen years, frequently using lead. For the past four years he had been complaining of generalized weakness, constipation, loss of appetite and gradual loss of weight. A diagnosis of chronic plumbism had been made and, although he had been removed from all exposure to lead during the past three years, he still continued to complain of constipation and weakness and it was alleged that his symptoms were due to lead poisoning.

Examination—The physical examination showed nothing abnormal. The man was distinctly underweight and had a slight secondary anemia. The blood pressure was 150 systolic, 92 diastolic.

⁷ Gussierow A. Untersuchungen ueber Bleivergiftung. *Virchows Arch. f. path. Anat.* 21: 443 1861 quoted by Aub et al.¹

In the control studies there was no lead in 950 cc. of urine and 0.2 mg of lead in 62 Gm of feces. The blood showed red blood cells, 4,100,000, hemoglobin, 76 per cent. No stippling was seen.

Treatment and Results—The "deleading" treatment consisted of a low calcium diet, phosphoric acid, 5 cc. once every hour for twelve doses daily in a glass of water, and magnesium sulphate, one-half ounce every morning.

A specimen of urine forty-eight hours after treatment was instituted showed 0.1 mg of lead present. Subsequent studies every forty-eight hours showed from 0.1 to 1.2 mg of lead per thousand cubic centimeters of urine. The urine at the end of two weeks showed no lead.

Examination of 50 Gm of feces showed traces of lead too small to estimate. At the end of two weeks there was no lead present.

The blood chemistry was negative carbon dioxide, 46 volumes per cent, calcium, 84 mg per hundred cubic centimeters, and phosphorus, 77 mg. The red blood cells showed no stippling at any time before, during or after the treatment.

Two subsequent examinations of urine after discharge from the hospital showed no lead.

CASE 3—History—S. M., a man, aged 45, had been employed for sixteen years as a smelter, constantly using lead. For the

Repeated examination of 50 Gm of feces showed from 1 to 2.6 mg of lead.

Stippling of the blood was seen occasionally on repeated study. After three weeks of treatment with the high calcium therapy (as recommended by Aub and his associates¹) for the acute toxic episode, the acute symptoms subsided. The blood pressure dropped from a systolic of 190 to 120 and the diastolic from 110 to 80. At the end of three weeks the patient was clinically well, although occasional stippling of the red blood cells was found to be present. A twenty-four hour specimen of urine showed no lead.

A "deleading" treatment was then instituted for a period of three weeks by means of a low calcium diet and the administration of phosphoric acid, 10 cc. every two hours for six doses daily, and magnesium sulphate, one-half ounce, every morning.

Daily examination of a twenty-four hour specimen of urine showed the presence of from 1.5 to 2.6 mg of lead. Fifty grams of feces, examined three times weekly, showed the presence of from 2.2 to 3.6 mg of lead. The secondary anemia remained unchanged. Stippling was seen frequently but not in increased amounts.

After three weeks' treatment the patient was discharged from the hospital and was placed on a high calcium diet. He reported weekly to the office. Blood studies showed a rather

The author is indebted to Miss Emma Baughman, chief dietitian of the Jewish Hospital, who calculated these diets. (From the Laboratory Handbook for Dietetics by Dr. Mary S. Rose.)

past few years he had had increasing constipation, occasional pain in the abdomen and increasing weakness. A diagnosis of chronic lead poisoning had been made about a year prior to his coming under my observation. However, he continued to work and was finally admitted to the hospital because of severe abdominal pain, anorexia with vomiting, marked constipation and general weakness. The abdominal symptoms, particularly the colic, had been getting progressively worse for two weeks prior to admission.

Examination—The patient was well developed, with a distinct pallor of the face and mucous membranes, a lead line on the gums and poor oral hygiene. The examination was otherwise negative. There was a distinct hypertension, with a systolic blood pressure of 190 and a diastolic of 110.

In the control studies there was a faint trace of lead, too small in amount to estimate, in 1,300 cc. of urine and 1.2 mg of lead in 50 Gm of stool. Examination of the blood showed red blood cells, 3,960,000, with hemoglobin, 76 per cent, and moderate stippling.

Treatment and Results—Treatment for the acute episode was instituted with a high calcium diet and the administration of calcium lactate, 1 drachm (4 Gm) once every two hours, calcium gluconate 10 cc., intramuscularly daily for five days, and magnesium sulphate, one-half ounce every morning.

A twenty-four hour examination of urine showed the presence of from 1 to 1.5 mg of lead (studies made every forty-eight hours). No lead was present at the end of the third week.

persistent anemia, with occasional stippling of the red blood cells. A faint trace of lead was present in the urine on three examinations. After one month of rest at home the patient was readmitted to the hospital.

Second Admission—The "deleading" treatment on the second admission consisted of low calcium-high phosphorus diets in ratios of 1-3 and 1-4, phosphoric acid, 5 cc., once every hour for ten doses daily and magnesium sulphate one-half ounce every morning.

Twenty-four hour specimens of urine showed amounts of lead varying from 2.8 to 3.9 mg. At the end of three weeks the urine still showed on an average, 1.5 mg of lead in a twenty-four hour specimen. Fifty grams of stool, examined three times weekly showed the presence of from 2.6 to 4.2 mg. of lead. Chemical examination of the blood was negative, calcium, 106 mg per hundred cubic centimeters, phosphorus, 88 mg, and carbon dioxide 57.4 volumes per cent. The blood pressure was from 118 to 130 systolic and from 70 to 82 diastolic.

During the period of the "deleading" treatment there was no return of any of the acute symptoms. The patient was discharged and placed on a high calcium diet. He did not return to work but was kept under observation. Repeated examinations of twenty-four hour specimens of urine showed faint traces of lead. At the end of three weeks no lead was present. The patient continued, however, to complain of weak-

ness and was treated for the secondary anemia. Occasional stippling of the red blood cells was noted. He was kept under observation for six weeks and then again admitted to the hospital.

Third Admission—The "deleading" treatment on the third admission consisted of a low calcium-high phosphorus diet in the ratio of 1-4 (3,000 calories) and phosphoric acid, 10 cc every hour for ten doses daily, viosterol (250 D), 5 mm every four hours, and magnesium sulphate, one-half ounce every morning.

A twenty-four hour specimen of urine showed amounts of lead varying from 18 to 27 mg. Fifty grams of feces examined three times weekly showed from 2 to 3.2 mg of lead. Examination of the blood showed red blood cells, 4,350,000 and hemoglobin 82 per cent. Occasional stippling of the red blood cells was seen.

After four weeks of the "deleading" treatment the patient was discharged. There were no subjective symptoms other than slight weakness. Subsequent studies continued to show small traces of lead in the urine with occasional stippling of the red blood cells. The patient will probably be hospitalized again for further "deleading" treatment.

These three case reports are illustrative of a group of nine individuals who were under observation and

sodes occurred in any of the patients, nevertheless I was cognizant of the danger of an active lead stream and a possible involvement of the central nervous system. The danger of active "deleading" was pointed out by Hegler,⁹ and also by Kehoe and his co-workers. Spinal fluid examinations were not done in any of the patients. In the studies by Rabinowitch and his co-workers,¹⁰ lead was found in the cerebrospinal fluid of persons known to be suffering from lead poisoning. Lead was also found occasionally in small amounts in patients not unduly exposed to the metal. More recently Conc and his associates¹¹ discussed the question of lead as a possible cause of multiple sclerosis. In my studies there was no indication that an active lead stream was responsible for an increase in subjective symptoms or the appearance of symptoms suggesting the involvement of the peripheral or central nervous system. It is reasonable to assume that during the process of "deleading" the lead stream is probably not as strong as during the period of absorption, when the individual is exposed.

treatment for chronic plumbism. Six of these patients had been exposed to the ingestion of lead for several years and had come under observation from six months to two years after a diagnosis had been made. It is reasonable to state, in view of the work of Kehoe and his associates,³ that there had been a gradual excretion of lead during this period. In these patients, as illustrated in cases 1 and 2, "deleading" for a short period of time was sufficient to show that they were not heavily "leaded." By virtue of the fact that no lead was found in the urine at the end of three weeks' treatment it could be implied that there was only a small amount of lead stored in the depots of the body. In the absence of any objective evidence of lead poisoning and in view of the laboratory examinations it was reasonable to assume that a diagnosis of chronic lead poisoning was not justified in these individuals. In the remaining three of this group, as illustrated by case 3, it was evident that a great deal of lead had been absorbed and was stored in the tissues. It was necessary to hospitalize these patients repeatedly in order to institute the "deleading." Arbitrarily from three to four weeks was set as a time limit for the active "deleading" treatment. Although no acute toxic epi-

From the experimental data of Aub and his associates,¹ one may conclude that complete "deleading" is not possible. However, with the low calcium and the high phosphorus therapy and the administration of either ammonium chloride or phosphoric acid, there is a means of estimating whether or not large amounts of lead have been absorbed and stored in the tissues and also a means of rapidly "deleading" individuals.

CASES ILLUSTRATIVE OF "DELEADING" IN SUBACUTE PLUMBISM

CASE 4—History—M. S., a woman, aged 25, had been soldering wires using lead for approximately six months, when she began to complain of occasional abdominal pain and general weakness. A diagnosis of subacute plumbism was made on the history of exposure and the presence of occasional stippling of the red blood cells.

Examination—On physical examination the patient was in poor general condition with a distinct secondary anemia, otherwise the examination was negative.

¹¹ Conc, William Russell C. and Harwood, R. U. Lead as a Possible Cause of Multiple Sclerosis. *Arch. Neurol. & Psychiat.* 31: 236-269 (Feb.) 1934.

Control studies showed no lead present in a twenty-four hour specimen (950 cc) of urine, a faint trace of lead present in 20 Gm of stool, and a blood count of red blood cells, 3,800,000, hemoglobin, 74 per cent, and platelets, 108,000. There was occasional stippling of the red blood cells.

Treatment and Results—"Deleading" treatment consisted of a low calcium diet and ammonium chloride 15 grains (1 Gm) every hour for ten doses daily, and magnesium sulphate, one tablespoonful every morning.

Examination of the urine forty eight hours after treatment was instituted showed a trace of lead present. Subsequent examinations showed approximately 0.9 mg of lead in a twenty-four hour specimen. After two weeks of treatment no lead could be found. Subsequent studies were negative for lead.

There was a faint trace of lead in the feces forty eight hours after treatment was instituted. At the end of two weeks, no lead was present. Subsequent studies at no time showed the presence of lead.

There was no stippling of the red blood cells on discharge from the hospital.

CASE 5—History—F. C. a man aged 31, had been employed as a painter at intervals during the past year and a half at which time he began to complain of occasional abdominal pain and constipation. A blood study had been done and a few stippled red blood cells were found. A diagnosis of lead poisoning had been made on this finding and on the suggestive clinical symptoms.

Examination—Physical examination was essentially negative. Control studies showed no lead present in a twenty-four hour specimen (1,400 cc) of urine and no lead present in 30 Gm of stool. The red blood cells numbered 4,800,000 with hemoglobin 92 per cent. Occasional stippling of the red blood cells was noted.

Treatment and Results—The deleading treatment consisted of a low calcium-high phosphorus (ratio 1-4) diet and sodium phosphate 4 Gm daily and magnesium sulphate one-half ounce every morning.

Forty-eight hours after treatment was instituted a trace of lead (too small to estimate) was found in the urine. At the end of ten days, after repeated studies no lead was found. In the feces 0.5 mg of lead was present in 50 Gm of stool. At the end of ten days no lead was present. No stippling of the red blood cells was seen.

There were four patients in this group in whom a diagnosis of subacute lead poisoning had been made. Exposure to the absorption of lead was for a comparatively short time (from two to six months), at which time when subjective symptoms and the finding of stippling of the red blood cells suggested the diagnosis of lead poisoning. Cases 4 and 5 are illustrative of the value of the "deleading" treatment in this type of case. Within two weeks the lead that had been absorbed was excreted and subsequent studies after discharge from the hospital failed to reveal the presence of any lead in the urine. In evaluating the results of "deleading" in this group it is important to keep in mind that these individuals had been removed from their occupation. Subjective symptoms would probably have disappeared gradually with the excretion of the metal, under treatment, however, a more rapid "recovery" followed.

"DELEADING" AS A DIAGNOSTIC PROCEDURE

CASE 6—History—R. G. a man, aged 56, had been employed as a compositor handling lead for almost forty years. At no time was there any history of an acute toxic episode. He began to complain of headaches, dizziness, occasional abdominal pain and diarrhea two weeks before admission to the hospital. A diagnosis of lead poisoning was made, based chiefly on his occupation.

Examination—On physical examination the patient was well developed and well nourished. There were no objective signs

of lead poisoning present. Muscular power was good. Neurologic examination was negative.

Examination of the urine in control studies showed no lead present in a twenty-four hour specimen (1,200 cc.), and no lead was present in 50 Gm of feces. The red blood cells numbered 4,820,000, with hemoglobin 90 per cent. The red blood cells were normal in appearance, no stippling being seen at any time.

Treatment and Results—The "deleading" treatment consisted of low calcium-high phosphorus diet in the ratio of 1-3 (2,600 calories) and sodium phosphate, from 3 to 5 Gm daily, and magnesium sulphate, one-half ounce every morning.

A twenty-four hour output of urine on repeated examination failed to show the presence of any lead. Examination of the feces every forty-eight hours failed to show the presence of lead.

As a diagnostic procedure, "deleading" may occasionally prove helpful. Two patients constituted this group and it was alleged that lead poisoning was responsible for the symptomatology. The diagnosis in both cases rested entirely on the history of occupation. The changes after "deleading" indicated that abnormal amounts of lead had not been absorbed. The value of this method as a means of diagnosis lies in the fact that one can determine whether or not abnormal amounts of lead are stored in the tissues. The exhaustive investigations of Kehoe and his co-workers³ showed that the normal adult American excretes lead at a rate of from 0.02 to 0.08 mg per liter of urine and at a rate of 0.03 to 0.1 mg per gram of ash in the feces. The mean daily output for various groups of normal individuals varies from 0.25 to 0.38 mg.

The finding of an abnormal amount of lead in this type of case does not necessarily mean that the lead is the responsible agent in producing the clinical symptoms. The finding of lead below the amount normally present or the absence of lead, is the important factor in excluding this heavy metal as the agent responsible for the symptoms.

COMMENT

The administration of a diet low in calcium and the addition of either ammonium chloride or phosphoric acid definitely causes an increased excretion of lead. The addition of a diet high in phosphorus⁴ aids in the excretion of the lead. In several cases of chronic plumbism the lead in both the urine and the feces was increased in amount after phosphate therapy was instituted. Experimental and practical experience bears out Shelling's opinion. The addition of a high phosphorus, high calory diet with sufficient vitamin content improved the general appearance, the nutritional requirements were adequate and the rate of excretion of lead was maintained. In the "deleading" treatment of our patients there is now being used the low calcium, high phosphorus diet with a ratio of 1-3 and 1-4 as already outlined.

In persons who have absorbed lead it is possible that waves of liberation occur from time to time and produce symptoms of clinical activity. This method of treatment presents a means of rapidly ridding the body of the lead that can be readily mobilized. Oliver,¹² who has had large experience, reports the finding of lead in the urine many years after the exposure has ceased. Metabolic or some other factors not yet thoroughly understood may be responsible for these occasional waves of lead excretion. The lead that has been absorbed and is released at certain periods can be much more rapidly

excreted at stated intervals with this type of treatment. Although complete "deleading" is not possible, as demonstrated experimentally,¹ nevertheless it is reasonable to assume that the lead excreted is a large fraction of the lead that has been absorbed. The "deleading" treatment may have to be repeated at intervals if there is evidence of continued excretion of abnormal amounts of lead.

It is advisable that all patients undergoing "deleading" treatment be hospitalized. Although I have observed no instance of an acute toxic episode arising during the course of treatment, such an occurrence is possible and strict supervision is therefore necessary. The failure of acute toxic symptoms to develop when there is increased lead excretion is further proof of the fact that there is no parallel between the absorption and excretion of lead and the toxic manifestations. The estimation of lead in the excreta is of aid only in proving whether or not abnormal amounts of lead have been absorbed. The "deleading" treatment furnishes a method whereby lead can be rapidly removed from the tissues. The period both of disability and of prolonged excretion can be definitely shortened.

SUMMARY

The "deleading" treatment definitely increases the rate of excretion of lead. In chronic lead poisoning it may be necessary to "delead" the patients at intervals if the rate of excretion indicates a marked degree of absorption. In subacute plumbism the treatment usually brings about a rapid recovery. The natural process of excretion is hastened and the period of disability is definitely shortened. The "deleading" process may be used as an aid in the differential diagnosis in individuals suspected of having lead poisoning. The absence of lead in the excreta or the presence of amounts that may be considered normal² excludes lead as a factor. The presence of lead in the excreta in amounts above normal is an indication of previous absorption but does not necessarily prove that the individual is suffering from lead poisoning.

As a result of my experiences, I am in agreement with Kehoe and his co-workers³ when they state that "the diagnosis of lead intoxication must continue to rest largely upon the skill and judgment in the elicitation and interpretation of clinical evidence."

Body Fat and Surplus Fuel—All body fat originates as surplus fuel. The body gains fat when, and because, it takes in more fuel than it burns. Any food which has any fuel value is fattening when added to a dietary which is already sufficient. And foods are fattening just about in proportion to their fuel values, for, as we saw in the last chapter, surplus calories whether taken as carbohydrate, fat or protein in the food tend to be stored chiefly as fat in the body. The largest amount of surplus fuel which the body will store as carbohydrates (chiefly glycogen in the muscles and liver) is only enough to yield about 1,500 calories, while each pound of body fat means approximately 4,000 stored calories. In many cases the body if persistently supplied with more food than it needs will store more and more fat to an almost unlimited extent. While fashion largely determines what degree of fatness is popularly regarded as an asset and what as a liability, yet we know from good medical evidence that the problem of optimal fatness is one of health as well as style. A moderate amount of fat is undoubtedly of benefit to the body, while quite as certainly too large a surplus is a burden and may become a danger.—Sherman H. C. Food and Health, New York, Macmillan Company, 1934 page 38.

CONTROL OF LEAD POISONING IN THE WORKER

ELSTON L. BELKNAP, MD

MILWAUKEE

Because of the inability of engineering to eliminate lead exposure at its source, the scientifically proved method of control by Aub and his associates has been applied to lead absorption and its acute toxic episodes in the supervision and treatment of approximately 500 cases of lead exposure, 200 of absorption, and 100 of intoxication.

The present demonstration of these principles has been effected by a diagnostic division of cases into absorption (1) plus severe intoxication requiring hospitalization, (2) plus mild intoxication, not disabling, (3) plus only laboratory signs of intoxication, and (4) without even laboratory signs of latent intoxication.

Except for the first actually disabled group, the other three potentially disabled groups have been treated with the worker at work. Such treatment must (1) start before disability, (2) utilize calcium advisedly but not as a routine, and (3) consider under perfect laboratory and clinical control that artificial deleading is superior to spontaneous uncontrolled deleading.

Following my study and treatment of a few cases of lead poisoning, published five years ago¹ and based on the work of Aub and his co-workers,² I was asked in October 1930 to make a survey of a storage battery plant and to make recommendations to the officials concerning the lead hazard. At first I considered it a housecleaning job in which I had the usual problem of remedying what damage had already been done. That my survey should develop into a problem of controlling lead poisoning, a matter of prevention and in my own field of internal medicine, was beyond my hope. I still see no reason to discard any of the principles of treatment laid down by Aub and since further elaborated by him,³ although I have enlarged my experience to include about 500 cases of lead exposure, more than 200 cases of considerable lead absorption, and more than 100 cases of lead intoxication in various industries, besides this personal supervision of a group of workers in a storage battery plant. I am now convinced that these principles may even be applied as the basis for a practical control of lead poisoning.

Whether I am justified in considering this a successful solution may be judged by the following:

1 The initial study showed this to be a distinctly better than average battery plant, employing at any one time about 100 workers, exposed to considerable lead oxide inhalation in spite of relatively good engineering precautions.

2 There were six cases of real lead intoxication causing disability with compensation arising in my first three months of service. Previous to my survey of

3 There are now one or two cases of disability a year in the 100 workers. In fact, in contrast to the six cases arising in my first three months, and credit

Fig 1 —Form used in making examination previous to employment.

The first precaution in our method of control is a stringent preemployment examination by the physician himself (fig 1). The family history is unusually important, since individuals with a constitutional defect of early degenerative cardiovascular disease, diabetes, thyroid or other endocrine dyscrasia are not good can-

The preemployment survey must of course include a very complete physical examination (fig 2). The lead line in the gums is the most obvious feature to look for. Unfortunately, many family physicians are unfamiliar with it and are likely to regard any gum discoloration as a "suggestive lead line." Although its intensity may vary, this is one finding of which one can say absolutely that it either is or is not present. With the aid of proper illumination and a lens, one can make no mistake in determining the presence of the characteristic line of dots in the gum near teeth which are carious or surrounded by active pyorrhea. I have found that the lead line usually appears when the stipple cell count is from 10 to 20 for fifty fields (from 1,000 to 2,000 per million red blood cells). The exact technique for the gum examination has been well described by Aub.³⁰ It is amusing to hear some industrial surgeons

Fig 2—Form used in making examination previous to employment.

still proclaim that one of their main methods for the prevention of lead poisoning is strict attention to dental hygiene. The fact is that poor oral hygiene merely serves as a very convenient though not desirable indicator of lead absorption. As a rough test for an emergency diagnosis, I am convinced that the absence of a lead line in a pyorrheal gum indicates that there is very little, if any, free lead circulating. I have seen this borne out by quantitative twenty-four hour urine

4 Lead Poisoning in a Storage Battery Plant Pub Health Bull
205 June, 1933

It is of vital importance that the physician give the reexamination history himself so that he may establish and continue a close personal relationship with the worker in order that the latter may confidently tell the doctor of his slightest physical discomfort. It is only in this way that one can discover and give prompt treatment not only to incipient lead intoxication but to the apparently mild intercurrent illness that may precipitate

Fig 4—Form used to record physical examinations

After a personnel of excellent physical quality has been developed as a result of these stringent preemployment examinations, the next precautionary step in the control is that of periodic reexaminations at least every two weeks to three months, according to the intensity of exposure. I have found the form shown in figure 3 practical. It includes symptoms grouped according to the three most important systems involved

Included in these frequent periodic reexaminations there must be a record of laboratory studies. Complete blood counts and routine urine tests as well as an estimation of lead in the twenty-four hour urine should be done at least every six months, and oftener in selected cases. Such quantitative estimation of lead in the urine may bring surprising information as to the amount of

absorption, even in the so-called insusceptible individuals. The method of Fairhall, with modifications noted in the U S Public Health Bulletin,⁵ has proved satisfactory as used by our chemist. According to the work of Dr Kehoe,⁶ the so-called normal amount of lead in the twenty-four hour urine of a worker who does not work with lead may be 0.08 mg, and even 0.15 mg may be a sign of nothing more than the expected absorption that may be safely permitted in a lead worker.⁷ I have found this limit of 0.15 mg to be safe and also that anything above 0.2 mg should be considered abnormal and requiring investigation.

Whenever a man is reexamined, a hemoglobin and a stipple cell count must always be made. I pay most attention to the stipple cell count, because, if one waits for a real anemia with hemoglobin below 80 per cent or red blood cells below four million, the patient may be on the verge of an acute episode such as lead colic, which can then hardly be avoided. The presence of a few stipple cells (from 5 to 10) in fifty fields (from 500 to 1,000 stipple cells per million red blood cells) does not necessarily indicate anything more than lead absorption. A man may continue for years with such a count without lead intoxication or acute lead poisoning. But if the stipple cell count leaps up from day to day, 20, 50, 100, 200, 400 in fifty fields, an acute episode is impending that may still be prevented. This episode is not due necessarily to any added exposure but most often to an infection disturbing the acid base equilibrium with resultant increased circulating lead. In my own experience it has been an acute infection that has precipitated every spontaneous episode of acute lead intoxication. It is at seasons when infections of the upper respiratory tract are prevalent that one must be most watchful. As I have said before, the early discovery and treatment of even the most apparently insignificant

treatment may be changed immediately, if necessary, and recommendations made for further precautions against exposure. It is advisable that the physician insist on the proper wash room and lunch room hygiene and that he suggest milk between meals, but it is more important that he himself keep the closest supervision of his men at their actual work stations so that he may visualize the exposure of each when he examines him later in the medical department. He must also be on

Fig 7 (case 2)—This illustrates the second type with mild symptoms of weakness, vague abdominal distress and loss of weight but no real disability but with definite laboratory signs of intoxication treated in the usual manner with calcium and iodide therapy. The man was exposed for three and one half years to heavy lead inhalation but used a plain respirator for two and a half years of this time. It shows a recurrence of lead line and stipple cells following first course of deleading coupled with infection but he has passed through several bouts of infection since without stirring up signs of lead intoxication. He showed decided improvement a month before he was moved to less intense exposure. He has had no recurrence of symptoms or signs for the past year. He has gained 10 pounds (4.5 Kg.) and his twenty-four hour urine is well below 0.15 mg. even though he is still exposed to moderate but definite lead absorption.

the alert for unexpected sources of exposure by frequent and unannounced inspection of the plant itself, so that he may be sure that adequate suction devices are being used where needed and that men have been shifted to less hazardous positions or given increased respirator protection according to his recommendations. Such broad measures for protection of the worker against industrial poisoning agree, I believe, with the principles so succinctly epitomized in the recent monograph by Hamilton.⁸ The result of my analysis of this plant inspection and of the periodic monthly medical report has proved to me, for example, that equipping a man with a positive pressure or air line respirator is equivalent to moving him from exposure to lead. This greatly simplifies but does not do away with the necessity of treatment, for I have seen many men whose lead exposure antedated the development of this protection.

The actual treatment of lead absorption and intoxication, I find, concerns itself with four types of patients. The first type (figs 5 and 6), which is now becoming rare but which was considered inevitable until recently, is that of the worker with heavy absorption plus a real intoxication with temporary disability from colic, palsy, or even encephalopathy. The treatment for this is still the one based on Aub's research and described in my earlier paper, but with certain practical modifications, such as

1 Immediate hospitalization with intravenous calcium gluconate, instead of chloride, 50 cc of the 5 per cent solution

8 Hamilton Alice Industrial Toxicology New York Harper & Bros 1934

Fig 6 (case 1)—This type of severe intoxication with disability is shown graphically by a chart which includes the subsequent courses of deleading and the final decrease of lead in twenty-four hour urine to below the safe limit of 0.15 mg.

nificant infection is one of the most important methods of control.

The results on the periodic examination must be analyzed frequently by the medical consultant so that

7 Kehoe, R A Thammann Frederick, and Cholak Jacob Lead Absorption and Excretion in Certain Lead Trades J Indust Hyg 15 306-319 (Sept.) 1933

The third type (fig 8) may show only a lead line, with laboratory signs of lead absorption and intoxication. This is long before there are any symptoms at all. The treatment is identical with the one just described. This group is named here because it is remarkable that there should be such unmistakable warnings of intoxication discoverable only by the laboratory without any premonitory symptoms and yet be so susceptible to prompt treatment, preventive of any disability even in the face of continued exposure.

The fourth type (fig 9) consists of the so-called good risks, of workers who have no signs of absorption, not a clinical symptom and not even apparent laboratory signs of latent intoxication but who, I have found, may show stored lead if given provocative treatment with iodide or some other deleading agent

Fig 9 (case 4) —This example of preventive treatment shows not even laboratory signs of latent intoxication until lead excretion has been stimulated by prophylactic chelating. Even though it has been as yet feasible only to supply this man with a plain respirator, he has had heavy and continuous lead oxide exposure for four years, is an unavoidably hazardous work station where disabling lead colic has consistently developed in other men. He has had several infections with no deleterious effects. He seems to belong to the group of apparently good risks. He has been absorbing excessive quantities of lead that should be disposed of under controlled conditions.

to be the logical final stage of treatment for all four types of lead absorption with or without intoxication

When I speak of deleading, I do not mean to give powerful deleading agents in the midst of an acute intoxication. This might provoke an encephalopathy. Neither do I mean that an individual is to be given deleading medication and then be discharged from treatment or the factory to continue the process indefinitely and unsupervised. I have certain definite criteria for deleading. I do not consider it advisable until all acute symptoms have subsided for a month, until the hemoglobin is 80 or above, until the red blood cell count is four million or over, and until the stipple cells have dropped to 10 or below in fifty fields (from 1,000 to 5,000 per million red blood cells) and have remained there for two or three weeks, and finally until the lead in the twenty-four hour urine is 0.15 mg or lower. This insures that no great amount of lead is freshly liberated from the skeleton to be superimposed on lead still freely circulating throughout the body.

For the first two or three courses of deleading, supervision is extremely close in order to note a possible return of symptoms or of the lead line with increase in stipple cells and lead in the urine. If these should reappear I am prepared to fix the lead again in a nontoxic form by high calcium intake. That the lead line does often reappear at first is to me a striking clinical proof of the efficacy of deleading. I do not delead oftener than once in four weeks, and preferably not oftener than once in six or eight weeks, with the first two or three courses of deleading. In this way I avoid the unfortunate consequences of cumulating fresh lead on a preceding tide of loosened lead that has reached

its peak at about two to three weeks after stimulation. For the same reason I do not prolong any course of deleading over three or four days. Though I have used them successfully in a few hospital cases I have not yet found it practical to use ammonium chloride and sodium bicarbonate or a low calcium diet to delead men who are actually at work, but it is very easy to give them their iodide drops twice a day, a safe, effective dose being 15 drops of potassium iodide or 7 drops of sodium iodide in saturated solution. Such doses may seem inadequate, but I have found from experience that they just avoid symptoms of actual iodism and that they gently stimulate lead excretion without any recurrence of serious signs or symptoms of lead intoxication.

Using this technic, I have found that it may take from six to fifteen courses of deleading to free the individual of his most loosely combined and therefore most dangerous lead. After this, further prophylactic deleading or even the acidosis of acute infection usually fails to stimulate an increase of lead in the twenty-four hour urine above 0.15 to 0.2 mg. so that it is unlikely that there will be any recurrent toxic episodes of lead poisoning.

SUMMARY AND CONCLUSIONS

My own experience, then, causes me to believe that

1 This type of medical supervision is a highly specialized form of work, although it requires the broad background of internal medicine.

2 One must still have a workable course of scientific treatment of lead poisoning to care for workers until the engineers have made lead absorption impossible.

3 I have here presented a clinically proved and detailed method for the control of lead poisoning in the worker at work.

4 One should not wait for disability before one starts treatment.

5 Thoughtless and wholesale calcium treatment may be unwise, but when given advisedly it is of specific aid.

6 Even the so-called insusceptible workers may have relatively large quantities of stored lead ready to be liberated by natural or artificial means.

7 With perfectly controlled technic, in selected cases, artificial deleading of cases previously heavily loaded with lead is a benefit not only to industry but also to the worker, and it is safer than uncontrolled spontaneous deleading.

ABSTRACT OF DISCUSSION

ON PAPERS OF DRS LANZA, AUB, KEHOE, THAMANN
AND CHOLAK, JONES, BELKNAP AND GRAY

GEORGE H. GEHRMANN, Wilmington, Del. The presence of lead in normal urine, well demonstrated by Kehoe, Thamann and Cholak, has been of great help to many in industry. Dr. Belknap mentioned that the cooperation of the officials of any industry is most important that without cooperation it is impossible to accomplish any real work in the prevention of lead poisoning. I agree with the author that the history is important. The man is on the spot. He wants a job and he is afraid that any information that he may give concerning himself may result in his being unable to take up that particular line of work. Too much dependence should not be placed on the history. I have had cases of active pulmonary tuberculosis, as proved by physical and roentgen examination in which any symptoms whatever were denied. The author did not mention in his discussion of lead absorption and lead intoxication frequent air analysis at the site of the operation and at various

sites in that particular operation, which will often reveal valuable information as to the source of contamination of the supply of lead dust or lead fumes. I have been taking measurements of the extensors and the flexors of the wrist but have been unable to deduce any really valuable information from this test. After going over several years of work and many thousand tests, I decided to discontinue them. I do not practice deleading in any of my cases. I make a definite attempt to mobilize all lead in those cases which show signs of lead intoxication.

DR. PAUL A. DAVIS, Akron, Ohio. The method presented by Dr. Belknap is very much in accord with the method I have used for the last ten years in dealing with lead workers. There are three important factors in this problem: (1) employing only physically fit persons on lead work and those with good dental conditions, (2) frequent examinations of blood, urine and blood pressure, and (3) maintaining a proper ventilating system and personal hygiene. The main object in all industrial toxicosis is prevention. I have kept an individual chart in some cases for the last ten years and have correlated the stippling of red cells with the symptom complex, urinary tests and general physical condition and have found that this is the most accurate method for determining the absorptive index in lead cases. If the physician can have his finger on all the data there is little excuse for the development of a case of lead poisoning, but he must be able to interpret the clinical conditions found and know when to remove an individual from exposure and when to institute treatment. The eliminative process is influenced as to the function of the various organs and especially as to whether the system is bordering on an acidosis or alkalosis. If acidosis is present, more soluble lead is present in the circulating body fluids and severe symptoms may develop if this acidosis is very high. If severe symptoms are present, the logical procedure is to produce an alkalosis and drive the soluble lead out of solution or produce insoluble compounds that are less toxic. This is done by using calcium gluconate for immediate relief and diet for further improvement. Then a mild acidosis should be produced and elimination increased until the patient is cured.

DR. MILLARD KNOWLTON, Hartford, Conn. A more harmonious view concerning governmental participation in matters of this kind can be reached if the situation is considered more closely. Instead of combining the compensation phase of the matter with the research and advisory aspects, if the research and advisory work can be kept separate from the compensation work, with legal restrictions prohibiting the use of information obtained by research and investigation, and the use of reports of occupational disease in compensation cases and court cases, the industries will seek advice and carry out recommendations for correcting conditions. We have had that experience in Connecticut, where the law provides that information obtained through investigations by representatives of the state department of health, bureau of occupational diseases, cannot be used in court action or in compensation cases, nor can the reports of occupational diseases be used in such cases. Under these conditions our bureau has been able to work on a basis that puts its service in demand. Industry is coming to it for advice and is asking the bureau, with its laboratory facilities and trained men to investigate conditions and recommend corrective measures when necessary. Working on this basis, we do not find that governmental agencies are antagonistic to industry.

DR. ELBRIDGE J. BEST, San Francisco. I wish to ask a question. If I understood correctly, it was mentioned that there were respiratory symptoms that were as important as the gastro-intestinal symptoms. If that is so, I should like to have it explained. In San Francisco, bridges are being built. The steel is covered with lead and several workers have been leaded. There have been a large number of respiratory diseases naturally precipitating a certain percentage of lead cases, and a number of them have been brought before the industrial accident commission as lead in which no lead has been found, and it would be helpful if a little could be said on that point.

DR. A. J. LANZA, New York. I will answer the doctor's question. The statement I made was that in ordinary experience of disability among working people the respiratory diseases

outnumber the gastro intestinal. That is the average experience. There are almost three times as many cases, or claims for colds, influenza, pneumonia and bronchitis as there are for diseases of the gastro intestinal tract, but if in any industrial plant absenteeism on account of illness is due more to gastro-intestinal disorders than it is to respiratory disorders, it is well to keep in mind the possibility of lead poisoning.

DR ROBERT A. KEHOE, Cincinnati. Deleading as a diagnostic measure is, in my opinion, unwarranted. It is my belief, based on observations, that the average normal adult has in his tissues somewhat more than 100 mg of lead. Suppose that deleading is undertaken as a diagnostic procedure. Though lead exposure is suspected, normal quantities of lead are found in the urine and feces. An effort is made to promote excretion, and if the methods work—and I must stress the fact that in my opinion evidence for this is not very good—there is a rise in lead excretion. How, then, shall it be interpreted? In treatment of lead poisoning by deleading, one removes in a short time, comparatively, an amount representing only a small proportion of the total lead in the tissues. It takes from six to twelve or eighteen months for the abnormal amounts of lead in the leaded individual's tissues to be excreted naturally. If an attempt is made to delead in a week, two weeks, a month, the rate of excretion may perhaps be doubled or trebled, 35 or 40 mg will have been got out of the tissues, and 200-300, up to 1,000 mg will have been left behind. I don't want to stress the point in theory, but in practice I question the advisability of elevating lead excretion temporarily. One runs a certain risk of producing symptoms not only immediately but also possibly later, and one runs that risk for what seems the slight and evanescent advantage of avoiding a very slight delay. Dr Lanza spoke of the possibility of latent lead poisoning appearing two or three years after exposure had ceased. I have yet to see a case presenting a history of severe exposure and an interval of two years or more between cessation of exposure and death in which more than the normal residue of lead was found in the tissues. On the basis of such evidence as I have—confined to the study of some eight or ten leaded individuals—I have concluded that in a period of from twelve to eighteen months the total lead has been eliminated to what is practically a normal level.

DR R. R. JONES, Washington, D. C. Some American clinics and those on the continent of Europe are stressing the fact that reticulocyte counts are more important than are stippled counts for this purpose, since the latter are but one form of the reticulocyte. Whitby and Britton have shown this experimentally. They gave lead salts intravenously and on the fourth day found a maximum rise in the reticulocytes to about 30 per cent, while later, about the sixth day, the maximum stippled cell count was reached, and it was only about 8 per cent. Second injections two weeks later gave an immediate rise in the reticulocytes again, while the stippled cells remained about constant. They also showed that the stippled cells appear in waves, an increase in them being at the expense of the diffuse polychromatic cells. There is no definite distribution of stippled cells. I have seen men with stippled cell counts of more than 3,000 not ill but later go on compensation for plumbism with stippled cell counts of but 50 or 60. It would seem therefore that this variable stippled cell count cannot be as dependable as the reticulocyte estimation. If the stippled cell is a reticulocyte and there is but 8 per cent as compared with 30 per cent of total juvenile cells, surely one gets early evidence of this increase in reticulocytes prior to that obtained by watching for stippled cell increases. Stippled cells are easily estimated, and as a manifestation of lead poisoning they are of definite value in studying a case of lead intoxication. They are evidence of a disturbance in calcium metabolism. Giving calcium intravenously will cause a disappearance of this stippling, while such treatment will not influence the reticulocyte count at once. High calcium diets exhibit the same effect on the stippled cell.

DR ELSTON L. BELKNAP, Milwaukee. Dr Gehrman has emphasized the value of air sampling in the prevention of lead poisoning. I have been doing that and expect to produce a more detailed paper on that basis. It is the ideal method as a check on one's engineering and medical control. Dr Knowlton speaks of state control. Medical societies in Wisconsin are

taking the initiative in investigating industrial conditions so that the fundamental control remains in the hands of the physician in practice. Dr Kehoe has brought up a very natural objection to the value of deleading, but I have found it safe in my own experience. I have followed cases for two and three years after deleading and have found that deleading does keep a man within safe limits even in continued exposure. The cases described today represent many others. I expect to continue deleading under definite criteria. I must repeat that if physicians do not delead workers, nature is sure to do it in an alcoholic episode or in an acute infection. It still seems wiser to attempt deleading when the process can be controlled, especially since the worker is being kept at work where he remains exposed to lead. I hope in this way to keep pace with the small amount that he absorbs from day to day. I do not attempt to get rid of any but the most loosely combined lead and only small amounts of that. I expect to use the reticulocyte count described by Dr Jones and correlate it with my stipple cell curves. I wish to repeat that the stipple count is valuable when one watches its curve for a sudden rate of rise, a sure prediction of impending intoxication. Dr Davis in his experience agrees with this. Low calcium and acid diets for deleading, described by Dr Gray, have borne out Dr Aub's research but are feasible only when hospitalization is possible, in my experience. Deleading is not to be considered other than an emergency measure while the worker continues his exposure to lead. The ideal method is to move the worker or, if that is not possible, to increase his calcium intake for a while. The physician's work in industry is to deal with the practical necessity of keeping the worker well while he continues his hazardous occupation. In this way they can best cooperate with the management for every one's benefit.

DR IRVING GRAY, Brooklyn. The two slides shown by Dr Kehoe of the amount of lead obtained respectively from the tissues of an infant after death and from a male adult after death, neither having been exposed to lead, is eloquent proof of the fact that the average normal human being absorbs and stores lead in the system. In the process of deleading, it is reasonable to assume that all the lead that can be readily mobilized is excreted. The probability is that some lead remains in the tissues, as was shown experimentally by Aub. The lead that is retained is firmly fixed in the tissues and is innocuous. In view of Dr Kehoe's observations at autopsy, it would seem logical to expect that under the deleading treatment this heavy metal would be found in the excreta of individuals not unduly exposed. My experience has shown that lead is present in urine and stool after deleading treatment only in those who have absorbed abnormal amounts. In contentious cases in which all clinical signs of plumbism are absent, the low calcium, high phosphorus diet and the institution of phosphate therapy (deleading treatment) has a definite place. Under a hospital regimen the diet can be controlled, the patient can be carefully observed and the rate of excretion can be determined. As an aid in the differential diagnosis, deleading is distinctly of value.

DR JOSEPH C. AUB, Boston. I should like to say a few words in regard to the new evidence developed by Dr Kehoe in his discussion. It is important to remember that the source of readily available calcium which is easily liberated from bone is a small source. These trabeculae are easily replaced as well as easily liberated. Most of the weight of calcium in the body is in the solid cortical bone. Though lead may also be stored here, I do not think that various methods of depleting bone greatly disturb the regular metabolic replacement of this solid portion. The calcium and lead pulled from bone in acidosis, in dietetic abnormalities, or in abnormalities of the internal secretions come largely from the fine bony trabeculae scattered through the bone marrow. These trabeculae are not large but I think it is the lead stored in them that precipitates episodes such as Dr Belknap described as occurring with acute infections or metabolic upsets. The value of deleading consists of eliminating the lead in this readily available supply of bone salts, and replacing this calcium-lead mixture with uncontaminated calcium by means of milk and a high calcium-phosphate diet. If this is done, future metabolic demands on the bone salts will liberate a store that is not thoroughly impregnated with lead but has been purified by therapy.

Clinical Notes, Suggestions and New Instruments

INTERNAL DERANGEMENT OF THE KNEE AND SLIPPING PATELLA

SIMULTANEOUS OCCURRENCE IN THE SAME KNEE

FRITZ TEAL M.D. AND H. WINNETT ORR M.D.
LINCOLN, NEB.

Internal derangement of the knee joint due to tearing of the internal lateral ligament and detachment of a portion of the internal semilunar cartilage is a common disability. Recurrent slipping of the patella, however, is rather unusual and, when the two conditions occur in the same knee at the same time a situation exists that calls for radical surgical relief. We report a case in which the foregoing conditions were manifest and describe the method by which an excellent cure was obtained.

REPORT OF CASE

History—C. C. S., a man, aged 37, sustained an acute injury to his left knee in August 1930. Repeated aspirations yielded bloody fluid, and after three weeks the knee assumed its normal appearance. Pain persisted in the medial side and it was evident that the patient was suffering from a tearing of the internal lateral ligament and partial detachment of the internal semilunar cartilage. Operation at that time was advised but refused. He suffered repeated injuries to the same knee in the ensuing years.

March 23, 1934 he entered the office with a swollen and painful knee telling of an injury the night before. The knee was aspirated and a compression bandage applied. The knee responded readily to treatment, but convalescence was prolonged by the presence of another disability in the nature of an outward slipping of the patella. The latter disability was painful and annoying and kept him from his work. Operation was advised and performed a few days after.

Operation and Result—Under local infiltration, the quadriceps tendon and muscle were exposed from the patella to a point 6 inches above. The outer half of the tendon was separated for 6 inches and severed from its attachment to the patella well down on the outer border. A subcutaneous tunnel was made toward the inner side of the knee. Next the usual medial incision was made and the internal semilunar cartilage removed. It was found detached at its posterior third and greatly thickened. A stab wound was then made over the internal lateral ligament and the tendon as prepared was pulled through the tunnel and its free end sutured with heavy silk to the internal lateral ligament. The

A transferred outer half of quadriceps tendon B quadriceps tendon C patella D incision for removal of cartilage

deep fascia of the thigh was sutured to the cut border of the intact quadriceps tendon with chromic gut and the skin closed with plain catgut. The knee wound was closed in layers, care being taken to repair the capsule. A cast was applied from the toes to the hip, with the knee in 10 degrees flexion. The leg was suspended in a Balkan frame for a period of two weeks, after which time the cast was removed and passive motion was started.

After nine weeks the knee is free from swelling, and flexion and extension are normal in range. The transferred tendon has become adhered to the structures on the medial side of the patella and on extension puts a direct pull on the internal lateral ligament. The fibrosis in the region of the transferred tendon is sufficiently strong to prevent lateral displacement of the patella. The pain and disability in the knee have, on the patient's own statement, entirely disappeared.

TREATMENT OF A CASE OF CHRONIC VAGINITIS WITH PHENYLMERCURIC NITRATE

FREDERIC WADE HITCHINGS M.D., CLEVELAND

It is a matter of common knowledge that it may be extremely difficult to cure a leukorrheal condition. In attempting to do so, the first requisite is to determine the cause. This in itself may be no easy task, and success need not necessarily lead to cure. Bacterial infection, the invasion of parasites, and anatomic and even physiologic conditions all have to be considered. Often several factors from different sources act together in what may be a distressing condition for the patient. So-called remedies are numerous and too often are useless. The case reported here seems to be worth putting on record for two reasons. The first is that it resisted all efforts at treatment for five and one half years. The second is that cure finally was promptly, and apparently permanently, brought about through the use of douches of phenylmercuric nitrate.

In the fall of 1928 an unmarried woman in her late thirties had recourse to what proved to be an unfortunate expedient in using a cotton tampon instead of a menstrual pad during one of her menstrual periods. After the period was over, she removed, at least as she thought, all of the cotton. About a week later she began to have a profuse and foul vaginal discharge. As I was out of town at the time, she consulted a colleague who was caring for my patients. The colleague made a vaginal examination and found that part of the cotton had not been removed. He gave appropriate directions as to treatment, but the discharge persisted and in about a month the patient consulted me.

On further examination no particular changes were observed in regard to the condition of the uterus, fallopian tubes, ovaries and vagina beyond the fact that there was moderate reddening of the mucous membrane of the vaginal wall and the cervix. A few weeks later a rather severe acne of the face and upper part of the back appeared and persisted during the period of treatment. The question arose as to whether or not there might be any connection between the acne and the vaginitis.

Too much space would be required to give in detail all the facts connected with the case. Suffice it to say that as regards diagnosis, repeated examinations of smears failed to reveal any gonococci. *Trichomonas vaginalis* was never found. A colon bacillus infection was considered but could never be proved to be a cause. It was finally concluded that a *Staphylococcus albus* infection was responsible, owing to the predominance of this organism in the vaginal secretions and because it was found also in the acne pustules. It may be interpolated here that the pustules were deep, rather than superficial, in character.

As regards treatment, various solutions were used for douches of strength varying from very weak to as strong as could be tolerated. Physiologic solution of sodium chloride, boric acid solution, potassium permanganate, the brief use of corrosive mercuric chloride in a strength of 1/5,000, lactic acid, and compound solution of cresol were among those most thoroughly tried. Weak permanganate solution seemed to be the best, but only through affording more prolonged periods of cleanliness than the others.

Other measures consisted in application of 1 per cent mercurchrome to the vaginal wall, cervical canal, and interior of the uterus, and the use of tampons, trinitrophenol suppositories, 2 per cent iodine (tincture) on the vaginal wall and 10 per cent in the cervical canal, applications of 2 per cent glycerite of tannin and its use in tampons, and insufflations of powdered boric acid. The cervical canal was cauterized on several occasions with a saturated solution of silver nitrate or with trichloroacetic acid. Implantations of cultures of *Bacillus acidophilus* were tried over a considerable period of time, but the need of frequent douching with physiologic solution of sodium chloride to remove the foul secretions probably prevented any benefit.

As the foregoing as well as other measures utterly failed to cure, recourse was had to the use of a vaccine made from *Staphylococcus albus* from both the acne lesions and the discharge. From the facts that an injection was followed in a few hours by the acne becoming worse and the discharge more profuse, this seemed to have a certain amount of effect, espe-

cially as there was later temporary improvement in both skin and vagina. It was impossible, however, even giving a long series of injections and using local measures at the same time, to overcome the infection.

Early in April 1934 the patient's condition was as bad as ever. She was obliged to wear menstrual pads constantly. The discharge was very profuse and so foul that, unless unremitting care to douche at least twice a day was taken, the odor was noticeable. The vulva had become exquisitely sensitive. The general health was below par.

At that time, thanks to Dr. E. E. Ecker of Western Reserve University, I had already been using phenylmercuric nitrate for some months as a local antiseptic in a wide variety of conditions, and with gratifying success. Bactericidal efficiency seemed to be at a maximum, while tissue irritation was indubitably at a minimum.

The patient was instructed to take douches twice a day, using phenylmercuric nitrate in a glycerin solution of 1:1,500 diluted down to 1:20,000. From the first, the vaginal discharge began to diminish along with disappearance of the odor. It is impossible to say exactly when the discharge stopped, but at the end of three weeks it had been gone for several days. On account of the possibility of mercurial irritation of the mucous membrane and of the kidneys, the patient was told to discontinue the douches and await developments. To date and frankly, after such a history, to my surprise, there has been no recurrence of the vaginitis in six months. There has been complete restitution to normal. Moreover, the acne began to improve with the improvement in the local condition and is hardly noticeable at present. There has also been great improvement in the general health.

Judging from the fact that the discharge disappeared as a result of using the douches without any direct intracervical or intra-uterine applications, the infection was confined to the vagina. As surmised when the acne first appeared, that it was connected with the vaginitis seems apparent. It should be stated that at no time was evidence of mercurial irritation of either the kidneys or of the mucous membrane of the mouth found.

10026 Euclid Avenue.

THE USE OF SODIUM DESOXYCHOLATE FOR THE IDENTIFICATION OF PNEUMOCOCCI

EINAR LEIFSON, PH.D., BALTIMORE

During the course of a study of the effect of sodium desoxycholate on the growth of bacteria it was found that sodium desoxycholate dissolves pneumococci much more rapidly and completely than does bile. Although this observation was made entirely independently, it was subsequently found from the literature that sodium desoxycholate has been used for this purpose for some time by a number of people, especially in England.

As early as 1917, Mair¹ described a method for the preparation of desoxycholic acid and stated that its solvent action on pneumococci is very much more powerful than that of bile and the common bile salts. Some years later Mair² published a detailed discussion of the solubility of pneumococci in bile and bile salts. Swann and Cooper,³ in a publication on the use of sodium desoxycholate in the treatment of pneumococcal empyema, state that they have used sodium desoxycholate in place of bile for some years for the identification of pneumococci. Their technique is similar to that of Mair. Mair makes a stock solution of sodium desoxycholate of 10 per cent concentration in water. This solution is stable and need not be sterilized. One-tenth cc. of this solution is added to 5 cc. of the culture. Lysis usually occurs within five minutes.

In this laboratory we have used sodium desoxycholate in the diagnosis of pneumococci for a considerable length of time.

From the Department of Pathology and Bacteriology, Johns Hopkins University.

1 Mair, W. The Preparation of Desoxycholic Acid. *Biochem. J.* 11:2, 1917.

2 Mair, W. The Pneumococcus. Autolysis and Solubility in Bile. *System of Bacteriology*. Medical Research Council 2:168, 1929.

3 Swann, B. R. and Cooper, T. V. Treatment of Pneumococcal Empyema with Bile Salts. *Brit. M. J.* 2:1117 (June 23) 1934.

Our technique has been to add 2 drops of a 10 per cent water solution of sodium desoxycholate to 1 cc. of pneumococcus culture. The culture becomes perfectly clear in from two to five minutes. We have never found any streptococci that are dissolved by sodium desoxycholate, and, conversely, we have never found any pneumococci that are not dissolved by sodium desoxycholate. As stated by Mair, the pH of the culture to be tested must not be below 6.5. Below this pH desoxycholic acid will precipitate from the solution. The temperature at which the test is carried out is of little practical importance as long as it is kept below 50°C. Above 50°C. the autolytic enzymes, according to Mair, are destroyed and without the presence of these enzymes the pneumococci are not soluble in bile or the bile salts.

This test has apparently not been used much in the United States, and since it is so far superior and convenient as compared to bile it seemed worth while to publish this notice. The only source in this country seems to be Riedel-de Haen, 105 Hudson Street, New York.

CHICAGO

(Concluded from page 120)

THERAPEUTIC EXERCISE OF THE ELBOW JOINT

The elbow is a hinge joint. The trochlear surface of the humerus articulates with the greater sigmoid cavity of the ulna, the capitellum of the humerus with the cup-like depression of the head of the radius, and the lesser sigmoid cavity of the ulna with the circumference of the head of the radius. The articular surfaces of the elbow are in an oblique position, and this, together with the position of the bones of the forearm, forms what is termed the carrying angle. This is seen with the arm in complete extension and measures about 170 degrees, varying of course in different individuals.

The head of the radius, which is in contact with the capitellum of the humerus and lesser sigmoid cavity of the ulna, makes movement possible in any direction. This articulation and the distal radio-ulnar joint make possible pronation and supination of the forearm.

The ligaments that give added strength to the joint are the capsular and the orbicular. The capsular ligament has four thickened bands, the anterior, the posterior, the internal lateral and the external lateral ligaments. The orbicular ligament around the head of the radius holds it against the ulna.

The synovial membrane is very extensive, becoming most superficial on each side of the olecranon process.

The movements of the elbow joint are flexion and extension, owing to the obliquity of the trochlear surface, these are not in a straight line. Flexion is accomplished by the brachialis anticus and biceps, assisted by the muscles arising from the internal condyle of the humerus and by the brachioradialis. Extension is performed by the triceps and anconeus, assisted by the extensors of the wrist and fingers. The arc of flexion and extension varies from 120 to 150 degrees,

extension taking place in a straight line and being limited by the olecranon process of the ulna on the posterior side of the humerus, and flexion being stopped by contact of the muscles of the anterior surface.

Pronation and supination of the forearm take place at the elbow and at the distal radio-ulnar joint, as previously described, the radius rotates at the elbow, and the ulna at the wrist. These joints make it possible to rotate the hand through nearly 180 degrees. This, together with the 90 degrees rotation possible in the shoulder joint, makes a range of 270 degrees for the hand when the elbow is fully extended.

The muscles which supinate the arm are the biceps and the supinator brevis, and those which pronate are the pronator radii teres and the pronator quadratus.

While the arm is in a sling or splint, "muscle setting" can be commenced with the biceps and triceps, and the muscles of the forearm. "Muscle setting" is the contraction and relaxation of the muscles without moving the joints.

When the tenderness has subsided, graduated extension of the elbow may be started while the arm is in a sling. The sling is slackened so that the elbow may be allowed to extend about 20 degrees, and voluntary movement can be advised within that radius. When these movements are painless, the sling can be relaxed still farther from day to day.

If the patient complains of pain following this treatment and the range has decreased rather than increased, it is a sign that too much was attempted the previous day and is an indication that the joint is too actively inflamed to undergo this treatment.

For passive motion, the patient should be placed in a sitting position at the side of a flat, padded table, and a smooth board, which has been well powdered, placed on pillows to bring the arm to a level with the shoulder. The arm is removed from the sling with care and placed on the board. The arm is grasped by the operator with one hand just above the elbow, and the other hand takes hold of the wrist. The elbow joint is then moved very gently but firmly through its complete range of flexion and extension, only once. Spasm should be avoided.

In relaxed movements of the elbow, according to Mennell, the patient should be in a sitting position, the operator should be in a position to support the part without difficulty, and the motions should be a natural combination. One hand of the operator grasps the arm of the patient at the elbow and the other hand holds the patient's hand. As the forearm is flexed, the shoulder is extended and the forearm is supinated. When the movement is reversed, the shoulder is flexed and the forearm extended and pronated. Active assistive exercise should follow as soon as possible.

When the patient's arm is out of a sling, active home exercises may be begun.

EXERCISES FOR THE ELBOW

1 Lying on the face, the forearm supported by the operator over the edge of the table, the patient bends the elbow, with the aid of gravity, to increasing angles.

2 Lying on the back, the forearm supported by the operator, straighten from increasing angles.

3 Sitting, with the inner side of the whole arm resting on the table on powdered cardboard. (a) Bend the elbow by sliding the forearm along the table. (b) Start with the elbow bent, and straighten.

4 Sitting, with the back of the whole arm resting on the table, raise the forearm until the hand touches the shoulder,

and lower. Give resistance by putting pressure in front of the wrist, then back.

5 Sitting or standing, the arm at the side, raise the forearm until the hand touches the shoulder. (a) Book in hand, lift the book to the shoulder.

6 Sitting or standing, the arm at the side, weight in hand. (a) With the palm facing forward, bring the weight to the shoulder and lower to the side. (b) With the back of the hand facing forward, bring the weight to the shoulder and lower to the side.

7 Standing, grasp the rod or the ledge at full arm's length over the head, the palms facing backward, raise the body until the chin touches the rod.

8 Sitting, the back of the upper arm resting on the table, the elbow bent to a right angle. (a) The palm facing the shoulder, turn the forearm until the back of the hand faces the shoulder. (b) The back of the hand facing the shoulder, turn the forearm until the palm faces the shoulder.

9 Sitting, the forearm resting on the table, the elbow bent to a right angle. (a) The hand resting on the little finger, turn the forearm until the palm faces down. (b) Turn the forearm until the back of the hand touches the table. (c) The back of the hand resting on the table, turn the forearm until the hand rests on the little finger. (d) The palm of the hand resting on the table, turn the forearm until the hand rests on the little finger.

Occupational Therapy—Sawing is a valuable aid to flexion and extension. With the arms held tightly to the side, weaving baskets, sewing on cards, and rope splicing are excellent.

Using a screw driver gives pronation and supination.

THERAPEUTIC EXERCISE FOR THE HAND AND WRIST

The wrist is a double hinge joint and is capable of all movements except rotation. There are three distinct joints permitting movement of the hand: the radio-carpal, between the radius and first row of carpal bones—the scaphoid, the semilunar, and the cuneiform; second, the midcarpal joint between the two rows, having the trapezium, the trapezoid, the os magnum and the unciform; and third, the carpometacarpal joint between the distal row and the metacarpals. All these joints are of the condyloid variety. They are joined by the capsular ligament and four ligamentous bands, which are anterior and posterior, and the internal and external lateral. The last two are exceedingly strong and well defined bands, while the first two are weaker and fused with the capsular ligament.

The wrist joint movements are flexion, extension, adduction, or ulnar flexion, and abduction, or radial flexion. A combination of these movements produces circumduction. Flexion of the wrist joint is performed by the flexor carpi ulnaris, the flexor carpi radialis and the palmaris longus. The extensors of the wrist joint are the extensor carpi radialis longus, the extensor carpi radialis brevis and the extensor carpi ulnaris.

Radial flexion of the wrist, or abduction, is performed by the abductor pollicis longus, the flexor carpi radialis and the two radial extensors. The ulnar flexors, or adductors, of the wrist are the extensor carpi ulnaris and the flexor carpi ulnaris.

The hand can be flexed on the forearm from a straight and extended position about 90 degrees, but part of this motion takes place in the carpal bones.

Extension takes place through a range of from 45 to 65 degrees. Ulnar flexion of the wrist is about 45 degrees, while radial flexion is less, being limited by the styloid process of the radius.

The movements of the thumb are flexion, extension, abduction, adduction and slight rotation as it flexes toward the fingers and aids in bringing the ball of the thumb to meet the ball of each finger. The range of flexion and extension, abduction and adduction is about 90 degrees.

The flexor pollicis brevis, the opponens pollicis and the adductor pollicis produce flexion and opposition, two movements that are similar in character. The two special extensors, brevis and longus, and the abductor pollicis longus, produce extension. The abductor pollicis longus and the abductor pollicis brevis produce abduction. The adductor pollicis and the first dorsal interosseous muscle produce adduction. Flexion of the distal phalanx of the thumb is performed by the flexor pollicis longus, and flexion of the proximal phalanx is accomplished chiefly by the flexor pollicis brevis. Extension of the distal phalanx is taken care of by the extensor pollicis longus, and of the proximal phalanx by the extensor pollicis brevis.

Flexion of the distal phalanges of the fingers is performed by the flexor digitorum profundus, and of the middle phalanges by the flexor digitorum sublimis. The flexors profundus and sublimis both act to a slight extent on the proximal joints. Flexion of the proximal phalanges with extension of the interphalangeal joints is produced by the interossei and the lumbricales, which at the same time extend the second and third phalanges. Extension of the proximal phalanges is performed by the extensor digitorum communis, the extensor indicis proprius, and the extensor digiti quinti proprius. Abduction and adduction of the fingers are movements of the proximal phalanx away from and toward a line through the middle finger. The abductor digiti quinti and the dorsal interosseous muscles act as abductors of the fingers. The volar interosseous muscles operate as adductors of the little, ring and index fingers. In the middle finger the second and third dorsal interosseous muscles act alternately as abductors and as adductors.

In passive exercise of the wrist and fingers, proper combinations are as follows:

1 Flexion of the fingers should be combined with extension of the wrist.

2 Extension of the fingers should be combined with flexion of the wrist.

3 Extension of the wrist with pronation of the forearm.

4 Flexion of the wrist should be given as the forearm movement passes from full pronation to a position midway between pronation and supination.

In passive movements of the wrist, the arm is placed on a smooth board. One hand of the operator grasps the hand of the patient, and the other grasps the forearm well above the wrist. The wrist is then flexed as the fingers extend and the forearm passes from full pronation to a point midway between pronation and supination. This should be done very slowly and evenly.

For ulnar and radial flexion, the arm and the forearm are gently lowered to the board, still flexed at the elbow and at right angles, with the palm of the hand touching the board. Grasp the hand of the patient under the palm and, with the other just above the wrist, carefully deviate the wrist ulnarward, for it is best to start in this direction and then proceed radialward with slight pronation and extension.

For flexion of the fingers, place the forearm in the same position. The palmar surface of the operator's

hand covers the dorsal surface of the patient's hand, and the fingers of the operator cover those of the patient. The wrist is well supported and, if possible, in a dorsiflexed position. If the individual phalanges need attention, the procedure is much the same. For extension and hyperextension, the finger tips are pulled back. The operator should bring his fingers over the end of the patient's and then slowly and evenly pull them back. The thumb is flexed and extended, abducted and adducted, and later circumducted.

For pronation, supination, wrist, finger and thumb exercises we use a Kanavel table. Construction details will be supplied on request.

For active exercises for the wrist and hand the following are suggested:

EXERCISES FOR THE HAND AND WRIST

1 The hand resting on the little finger. (a) Bend the wrist forward, keeping the fingers straight. Give resistance by putting pressure on the palm near the wrist. (b) Bend the wrist back as far as possible, keeping the fingers bent. Give resistance by putting pressure on the back of hand near the wrist.

2 The hand resting on the table, palm down. (a) Move the hand toward the thumb. Give resistance by putting pressure on the thumb near the wrist. (b) Move the hand toward the little finger. Give resistance by putting pressure on the little finger side of the hand near the wrist.

3 The hand resting on the little finger, the wrist bent back to bend the fingers, and the wrist forward to straighten. Bend the fingers at the first joint, keeping the other joints straight. Give resistance by putting pressure just above the first joint.

4 The hand resting on the table, palm down. (a) Spread the fingers, being careful that the fingers are not raised from the table. Give resistance by grasping the fingers with the other hand. (b) Bring the fingers together. Give resistance by putting the fingers of one hand between the fingers of the other.

5 The arm resting on the little finger side of the hand, bring the tip of the thumb to the tip of each finger and to the first joint of the little finger, making a circle. Give resistance by putting pressure between the tips.

6 Repeat exercise 5, grasping a towel between the finger tips, using the other hand trying to pull the towel out of grasp.

7 Close all the fingers and the thumb to a tight fist and open fully. Repeat against resistance offered by the other hand.

8 The hand resting on the little finger and the forearm on the table, the elbow bent to a right angle. (a) Turn the hand so that the palm rests on the table. (b) Turn the hand so that the palm faces up, being careful that movement is not made in the shoulder.

9 Carry a book between the thumb and the fingers flat on the book, the arm at the side.

10 Carry the book on the palm of the hand, with the fingers straight.

11 Pick up a soft rubber ball, grasping and letting go. Decrease the size of the ball.

12 Wring out different sizes of cloth.

Occupational Therapy—Curative occupational therapy in the form of basket weaving, cutting tin designs with tin shears, leather work, painting, carpentry and other forms may be used effectively. All of these are used only after the wrist, hand and fingers have secured sufficient range and strength of movement. Before this a patient with a stiff wrist and fingers may be asked to wind cord into a ball.

THERAPEUTIC EXERCISE FOR THE HIP JOINT

The hip joint is of the ball and socket variety, having greater strength and less mobility than the shoulder joint. It is situated deep and is formed by the head of the femur articulating with the acetabulum of pelvis, produced by the union of ilium, ischium and pubes.

The iliofemoral ligament, which forms the anterior part of the capsular ligament, is exceedingly strong. It checks hyperextension and is very important in maintaining the upright position.

The chief movements of the joint are flexion, extension, abduction, adduction, internal rotation, external rotation and circumduction, the last being a combination of flexion, extension, abduction and adduction.

Flexion is produced by a forward movement of the thigh until it comes in contact with the abdomen, it being less when the knee is straight, owing to the checking influence of the hamstring muscles, which are placed on tension. The range of flexion with the knee joint flexed is 150 degrees or more, with the knee extended it is difficult to bring it beyond a right angle with the trunk. The muscles that flex the thigh are the iliopsoas, the rectus femoris, and possibly the sartorius and the tensor fasciae latae.

Extension is the opposite of flexion, and the limb is moved downward and backward. When it is in a vertical line with the trunk, it is stopped by the iliofemoral ligament and the pubofemoral band. Hyperextension is caused by the pelvis tilting backward with the movement of the femur, and the range is about 45 degrees. The chief muscles that extend the thigh are the gluteus maximus and the hamstrings.

Abduction is possible by moving the limb away from the other sideways and is about 50 degrees. The muscles that abduct the thigh are the gluteus medius, gluteus minimus and the tensor fasciae latae.

Adduction is the opposite of abduction and moves the limb through the same plane toward the opposite one, being stopped by contact with it. Adduction can take place farther by moving the limb in front of or behind the other, or when the trunk is inclined to the side. The range in this way can be increased 45 degrees. The muscles adducting the thigh are the adductor gracilis, the adductor longus, the adductor brevis, and the adductor magnus.

Internal rotation is produced by turning the leg inward and is checked by the ischiocapsular and posterior capsular ligaments. The range is about 30 degrees. The muscle producing internal or medial rotation are the iliopsoas, the anterior parts of the gluteus medius and gluteus minimus, and the tensor fasciae lata.

External rotation is accomplished by turning the leg outward and is checked by the outer band of the iliofemoral ligament. The range is about 60 degrees, and the muscles responsible are the piriformis, the obturator externus and internus, the gemelli superior and inferior, the quadratus femoris, the three adductors, the pectineus, the inferior fibers of the gluteus maximus, and the iliopsoas.

The complete range of rotation is about 90 degrees. A combination of flexion, extension, abduction and adduction produces circumduction.

The patient, lying in the supine position, should be completely relaxed for passive movement. The operator stands beside the patient, grasps the heel with one hand and places the other in the popliteal surface with the palmar side up. The knee and the hip are slowly, steadily and evenly flexed, and the hand in the popliteal space is slipped over the head of the tibia, is held for the count of five and is then slowly returned to position. This movement should not proceed to the point of inducing spasm.

Active assistive movements should be started along with passive movements, provided sufficient range has been established with the latter. It is well to start with flexion and extension. The patient is assisted to a lying position on the affected side, the sound leg being placed behind it. The patient is then told to flex the thigh and the knee at the same time, the operator gently assisting the movement by pushing against the posterior part of the thigh just above the knee joint, the knee and the thigh are then extended. This assistive movement may be necessary in the early part of the arc of movement and also in the latter third. Spasm should be avoided. Active assistive movement is followed by free movement in the same plane.

Active movements for rotation are the last active movements attended to. For this the patient is placed in a prone position, face down. The knee is then flexed by the patient to a right angle and he is told to turn the leg outward and then inward.

When sufficient range and strength of movement have returned, weight-bearing exercises may be given, first without apparatus and then with apparatus. Construction plans for home made apparatus will be furnished on request.

EXERCISES FOR THE HIP

1 Lying face down, the leg being supported off the bed, the knee straight, the patient tries to draw the knee toward the bed with the help of gravity (no resistance being used by the operator).

2 The patient lying on the back, the operator lifts the leg (the knee straight) and the patient forces it down.

3 The patient lying on the side to be exercised, a piece of powdered cardboard under the leg, the operator holds the other leg. The patient brings the knee to the chest.

4 Same as in exercise 3, except that the patient brings the leg back.

5 Lying on the back, the leg on a piece of powdered cardboard, move the leg directly sidewise, without lifting the foot keeping the knee straight and the foot up.

6 Lying on the back same as in exercise 5, except that the patient brings the leg in.

7 The patient lying on the good side, the operator holds the affected leg up, the knee straight, and the patient brings it down to the other leg.

8 Sitting with the knees bent the lower legs hanging, raise the lower leg to the side away from the other leg keeping the knees together.

9 Sitting with the lower legs hanging, raise the lower leg across in front of the other leg to the knee.

10 Lying on the back the heels on powdered cardboard, the knees at right angles, straighten the knees and return to the first position.

11 Lying on the back, the knees straight, raise both legs to an angle of 90 degrees and move them forward and back, alternating.

12 Lying on the back, the knees straight raise both legs to an angle of 45 degrees, then 90 degrees back to 45 degrees and to position.

13 Sitting the body erect the knees straight, reach forward and touch the toes.

14 Standing, grasp a chair for support, swing the leg loosely from the hip.

Exercise in the curative workshop with the bicycle saw, which can be run with various appliances to produce different exercises, and working on a foot loom.

THERAPEUTIC EXERCISE FOR THE KNEE JOINT

The knee joint is the largest and the most complex in the body. The great strength that the knee joint possesses is due largely to the ligaments and to a less

degree to the muscles, there being no interlocking or fixation of the bony elements. The capsular ligament is strengthened by the tendons passing over it in various directions and in addition by the internal and external lateral ligaments, which add to its strength. The joint is lined with synovial membrane of great laxity.

There are two crucial ligaments, the anterior and the posterior, which cross each other and firmly bind the femur to the tibia. There are two interarticular fibrocartilages, the larger internal and the smaller external. The former is thinner and subjected to greater strain than the latter.

The patella is roughly circular in outline, its superficial surface dome shaped, to which are attached the expansions of the quadriceps extensor. Its deep surface is irregularly flat, covered with articular cartilage. It has a sliding and rolling movement and prevents the tendon of the extensors from drawing into the groove between the condyles of the femur. The patellar ligament or tendon is inserted into the anterior tibial tubercle well beyond the joint.

The movements of the knee joint are flexion, extension and, in addition, rotation, both internal and external, when the knee is flexed 90 degrees or more.

Flexion is produced by bending of the knee joint, is stopped by contact with the thigh, and has a range of about 135 degrees. The muscles that flex the knee are the hamstrings, assisted by the gracilis, the sartorius, and indirectly by the gastrocnemius. Extension is the opposite of flexion, and the degree range is the same as that for flexion. The quadriceps extensor, aided by the tensor fasciae latae, is responsible for this action.

When the knee joint is flexed to 90 degrees or more, the tension on the ligaments slackens, permitting internal and external rotation of the tibia. This rotary action in the flexed position is of great convenience in climbing, and the lack of it in extension maintains a stable position on the feet. The inward rotators are the semimembranosus, the semitendinosus, the sartorius and the adductor gracilis. The outward rotator is the biceps femoris.

For passive movement, the patient is placed on the side with the knee on a smooth, powdered, rectangular board. The operator stands to the rear of the patient, grasps the ankle with one hand, and with the other firmly takes hold of the thigh just above the knee joint. The knee joint is then slowly, steadily and evenly flexed with the thigh to the point of spasm and held to the count of five. It is then extended in the same manner, care being taken not to extend it completely if pain is present.

Active movement should be started just as soon as there is sufficient range to make it practical. The injured limb is placed in the same position as that used for passive movement. The patient is then asked to flex his knee slowly, steadily and evenly. If any fibrillation occurs, movement should be stopped immediately and the operator should bring the limb back to its former position. At this point the operator assists the patient in flexing the limb in the first third of its arc of movement by gently placing one hand just above the ankle and then gently pulling. This is performed within the limit of pain. The leg is then extended, and assistance is given if necessary in the first and last thirds of the arc of movement by gently pushing the ankle on the posterior part.

Just as soon as assistance is not needed, free and resistive exercise are added. For increased resistive

work the pulley weights, the stall bars, the rowing machine, the bicycle, the balance beam and sandbags are used. There are three methods by which it is possible to obtain true free movement, namely, underwater exercise, the roller skate and the sling suspension methods.

Our curative occupational therapy for the knee joint is the bicycle saw, treadle saw, foot loom, stationary bicycle and rowing machine.

EXERCISES FOR THE KNEE

- 1 Move the knee cap without moving the knee, by contracting the group of muscles above the knee.
- 2 Lying face down, the knee bent, the foot supported by some one, straighten from increasing angles.
- 3 Lying on the back, the heels on powdered cardboard, the knee bent, straighten from increasing angles.
- 4 Lying on the affected side, a pillow between the thighs, the leg on powdered cardboard. (a) Straighten from increasing angles. (b) Tilt the cardboard to increase gravity.
- 5 Sitting on the edge of the table, the leg hanging. (a) Straighten the knee. (b) Add weight to the leg.
- 6 Sitting on the edge of the table, the leg supported by the operator, at horizontal, bend the knee.
- 7 Lying on the unaffected side, a pillow between the thighs, the leg on powdered cardboard. (a) Bend the knee through increasing angles. (b) Tilt the cardboard to increase gravity.
- 8 Lying on the back, the heels on powdered cardboard, the knee straight, bend to increasing angles.
- 9 Lying on face. (a) Bend the knee through increasing angles. (b) Add weight to the leg.
- 10 Sitting on the edge of the table, the legs hanging, swing the legs back and forth alternately.
- 11 Standing, bend the knees, raise the heels, keep the knees close together, and return to the erect position.
- 12 Bicycle riding.
- 13 Kneeling, sit back on the heels as far as possible.

THERAPEUTIC EXERCISE OF THE FOOT AND ANKLE

There are four sets of joints in the foot when movement takes place: the ankle joint, the tarsal joints, the tarsometatarsal joints, and the phalangeal joints.

The ankle joint is a hinge joint formed by the union of the astragalus and the lower part of the tibia with its internal malleolus and the external malleolus of the fibula. This joint is bound by thick, fibrous, capsular ligamentous bands thickened on four sides by strong bands called lateral ligaments. They are the stronger internal and internal lateral, and the lesser anterior and posterior ligaments.

The subastragalar joint, which is the joint between the inferior articular surface of the astragalus and the superior articular surface of the os calcis, is a double saddle joint allowing movement of the os calcis under the astragalus when the leg is fixed, or of the os calcis on the astragalus when the foot is fixed. The midtarsal joint is of considerable importance and consists of two parts, an outer and an inner one. The outer one consists of the calcaneocuboid and is a saddle joint permitting only a limited degree of flexion, extension, abduction and adduction. It possesses greater strength and weight-bearing qualities than does the inner portion. The inner part is the astragalonavicular and forms the instep above the longitudinal arch. It is a ball and socket joint and is capable of movement in all directions, including rotation. Owing to this fact it does not possess the strength of its outer component. The scaphoid articulates with the three cuneiforms, which in turn articulate with the three inner metatarsals, the two outer metatarsals articulate with the

cuboid These joints nearly all have flat surfaces, with gliding movements, which are limited by strong ligaments. The toe joints are the fourth set of joints and are of the hinge variety.

There are two arches of the foot, the longitudinal and the transverse.

The longitudinal arch consists of two parts, an outer less movable portion, and an inner one, which is more mobile, because of the ball and socket astragalonavicular joint. The outer component consists of the os calcis behind, the cuboid in the middle and the fourth and fifth metatarsals in front. It is supported by the heel behind and the head of the outer metatarsal in front. The inner component or more movable portion is an elliptic dome and consists of the os calcis to the rear, the astragalus and scaphoid, which form the top of the dome, and the three cuneiforms, and it extends to the heads of the three metatarsals but is supported by the head of the first metatarsal. There is no bony keystone to either the longitudinal or the transverse arch. Both are maintained by ligaments but depend in the last analysis on muscle action for their support.

The transverse arch fuses with the longitudinal components.

The most important ligament that maintains the arch of the foot is the inferior calcaneoscaphoid. The plantar fascia is of considerable strength and corresponds to a "binding rod" of the arch. The transverse metatarsal ligament is a narrow fibrous band connecting the anterior extremities of all the metatarsal bones.

There are three strong points of support, one extending from the heel to the head of the first metatarsal, the second from the heel to the head of the fifth metatarsal, and the third between the outer and inner metatarsals. Strong ligaments bind these supports together.

The movements of the foot are plantar flexion, dorsiflexion, eversion, inversion, adduction and abduction. The terms pronation and supination also are employed, pronation representing eversion plus abduction with some rotation at the calcaneoscaphoid joint, and supination representing inversion and adduction combined with rotation at the calcaneo-astragalar joint.

Dorsiflexion is the elevation of the front of the foot toward the front of the leg. Plantar flexion is a depression of the foot in a direction just opposite to that of dorsal flexion. Dorsiflexion and plantar flexion, chiefly in the astragalotibial joint, take place through a range of from 60 to 80 degrees. With the foot held at a right angle to the leg and the knee straight, dorsiflexion occurs through 10 to 20 degrees and plantar flexion between 50 and 60 degrees, the total range of both being from 60 to 80 degrees. With the knee flexed the range of dorsiflexion of the foot increases, and with the knee straight plantar flexion increases.

Adduction is a deflection inward of the forefoot from the mediotarsal and subastragalar joints. Abduction is a movement of the forefoot outward, which is just the opposite of adduction. Both adduction and abduction take place through the mediotarsal joint.

Eversion and inversion occur as a natural sequence with abduction and adduction. However, with eversion there is a definite lifting of the outer border of the foot, and with inversion a lifting of the inner border. These movements take place through the subastragaloid joint.

The muscles producing dorsiflexion are the tibialis anticus, the extensor digitorum longus, the extensor hallucis longus and the peroneus tertius. Plantar flexion is produced by the gastrocnemius, the plantaris, the soleus, the tibialis posticus, the peroneus longus and brevis, the flexor digitorum longus and the flexor hallucis longus.

Adduction and inversion are produced by the tibialis anticus, the tibialis posticus, the extensor hallucis longus and the flexor hallucis longus. Abduction and eversion are produced by the peroneus longus, brevis and tertius and the extensor digitorum longus.

The movements of the toes are mainly flexion and extension together with some adduction and abduction. Flexion is produced by the flexor digitorum longus and the flexor digitorum brevis. The lumbricales also flex but in addition draw the second, third, fourth and fifth toes medially.

Extension is produced by the extensor digitorum brevis, the extensor digitorum longus and the extensor proprius hallucis. Abduction and adduction are accomplished by the interossei.

Passive movement in dorsiflexion and plantar flexion may be commenced. The patient, lying down, is asked to turn on the side of the involved ankle. The sound limb is flexed and placed in front of the injured one, which is put on a smooth, well powdered rectangular board. The operator then grasps the ankle just above the joint with one hand and the foot with the other hand. The foot is then steadily, slowly and evenly dorsiflexed to the point of spasm and held for the count of five. It is then plantar flexed in the same manner.

Just as soon as sufficient range has been secured, active movement may be started. For active exercise of the sprained ankle, the patient should be placed in the same position as was used for passive movement, and on the same smooth, powdered, rectangular board. The patient should dorsiflex the ankle. This is followed by free and then by light, resistive exercise.

EXERCISES FOR THE FOOT

Exercises should be done slowly, carefully and smoothly. Rest between each exercise.

All except standing exercises should be done with bare feet. Do only the exercises on this list which are marked for you. Repeat the number of times daily as instructed.

- 1 Sitting, the knees crossed, the foot slightly turned in, pull the foot up.
- 2 Same position as 1, pull the foot in and up.
- 3 Same position as 1 (a) Curl the toes under, pulling hard. (b) Curl the toes under and pull the foot up. Keep the toes curled under. (c) Curl the toes under, pull the foot in and up. Keep the toes curled under.
- 4 Sitting, the foot on a board one inch thick, curl the toes over the edge. Try to touch the floor with the toes.
- 5 Lying on the back, the knees straight, the feet against the wall, the big toes together, the heels far apart, keep the heels against the wall and bring the forefoot away from the wall as far as possible.
- 6 Sitting, the big toes together, the heels far apart, raise the forefoot off the floor as far as possible.
- 7 Sitting, pick up marbles with the toes of the right foot and place them in your left hand, with the left foot into the right hand.
- 8 Sitting, spread a bath towel on the smooth floor, put the front half of the feet, the toes turned slightly in, on the edge of the towel, the heels far apart. (a) Grasp the towel with the toes of one foot and pull toward you, then with the toes of the other foot and repeat alternately, crumpling the towel under the foot. (b) Place a weight on the towel.

9 Sitting the knees apart, the legs crossed, rise, bearing the weight on the outer borders of the foot.

10 Standing, the toes turned slightly in, the feet parallel six inches apart, lift the inner border of the feet, relax half way and repeat. The toes cling to the floor.

11 Follow a straight line on the floor, walking on the outer borders of the feet, the toes curled downward and inward. Make the forward heel meet the backward toe.

12 Standing, lift the inner borders of the feet, rock backward and forward from heel to toe. Do not let the inner borders of the feet down.

13 Walk in a straight line so that the right heel strikes the floor first and the rest of the foot pivots inward 90 degrees. Repeat with the left foot.

14 Walk in a straight line so that the toes of the right foot touch the floor first and the rest of the foot pivots outward 90 degrees. Repeat with the left foot.

15 Standing, the toes turned in and curled under, the heels far apart, face the wall the toes 28 inches from it, place the hands on the wall, lean the body forward by bending the elbows. *Keep the heels on the floor the knees, hips and back straight.* Hold this position a few seconds.

RULES

1 When one sits always cross the ankles, resting the feet on their outer borders.

2 When standing always keep the feet parallel and the weight of the body equally on the two feet.

3 Walk correctly, the toes turned slightly inward at all times. This is as important as periods of exercise.

Committee on Foods

THE COMMITTEE HAS AUTHORIZED PUBLICATION OF THE FOLLOWING REPORT
RAYMOND HERTWIG Secretary

NOT ACCEPTABLE

KELVITA

MAGIC OF NATURE

The product Kelvita, manufactured by the California Kelvita Company of San Francisco, is, according to the package label, a mixture of dried kelp (a seaweed), wheat embryo and certain dried vegetables.

Discussion of Label and Advertising—The label states

'A natural food from California. Kelvita Magic of Nature a blend of kelp—wheat embryo—and vegetables presenting minerals and vitamins needed by the human body to maintain normal health and intelligence. Recommended in the treatment of deficiency diseases and glandular disturbances. One-half teaspoonful dry on the tongue swallowed with water twice daily. It is wise to be healthy. Calcium Copper Iron Magnesium Phosphorous Sodium.'

There is nothing really unique or even extraordinary nutritionally or otherwise, about this ordinary product. The ingredients wheat embryo (a part of all whole wheat foods) and vegetables are common market and table articles. The kelp an unpalatable seaweed, has found no place in the American dietary, there is no authoritative information showing a need for kelp in the diet. True kelp is high in iodine but sufficient iodine may be obtained from the ordinary mixed diet especially when iodized salt, now everywhere available, is used. Kelvita's 'minerals and vitamins' are readily obtainable from common market foods. More than minerals and vitamins are necessary 'to maintain intelligence'. The recommendation of the product for 'the treatment of deficiency diseases and glandular disturbances' is a vague misinformative medicinal claim. This, accompanied by the statement of dosage similar in form to such statements used for medicines represents an apparent attempt to transform a food into a medicine. What is meant by the vague designations 'deficiency diseases and glandular disturbances' is left to the imagination. This type of exploitation fosters self diagnosis and self treatment which may seriously endanger health.

The advertising not attached to the package, which is outside the jurisdiction of the federal Food and Drugs Act, assumes greater liberties. Some of the claims are:

Get Healthy Increase your happiness and vitality—lengthen your life with Kelvita, magic of nature. Protect it (your body) with Kelvita. Puts pep in your step. Probably one of the greatest and most sensible aids in regaining youthful vigor with every cell of the body tingling with effervescent vitality is thru eating Kelvita a balanced blend of concentrated vegetables.

treated with the natural ultraviolet and infra red rays from California's magical sun the body consists of some 12 or 16 organic minerals.

To maintain health this natural balance must be kept constant. A lack of one or more minerals results in deficiency diseases while a lack of several causes death. Constipation indigestion, worry, decaying teeth, lack of endurance and female disorders are sure signs of mineral deficiency.

The greatest accomplishments of Kelvita is in the treatment of CONSTIPATION ANEMIA RHEUMATISM NEURITIS LACK OF VITALITY PROSTATE GLAND TROUBLE GOITER NERVOUSNESS UNDERWEIGHT WORRY MENTAL DEPRESSION BACKWARD CHILDREN STERILITY OF BOTH SEXES and PROLONGED AND PAINFUL MENSTRUATIONS IN women. KELVITA is recommended as an accessory food in the treatment of these ailments is especially useful to prospective Mothers growing children and convalescents has brought gratifying relief to hundreds and was tested in a 1000 bed hospital.

'This is why KELVITA is available to you to furnish your body and those of your loved ones with vitamins and live food minerals that will so increase the resistance of each body cell as to throw off and keep out every disease. REMINERALIZE YOUR BODY.

KELVITA [is] very rich in food iodine calcium iron, phosphorous copper magnesium and traces of other minerals. IMPOR-

TANCE OF IODINE Your thyroid gland lies astride your Adam's apple is more active in women than in men. Your thyroid is

perhaps the most important endocrine gland of your body it controls your emotions. Its secretion is called thyroxin 65% iodine.

Possibly no life exists without iodine and normal life is impossible without 1/100 grain of thyroxin daily. Three and one-half grains of thyroxin

are all that lie between intelligence and imbecility. It has been observed that males fed a diet low in iodine are more difficult to arouse sexually

and females fed a no-iodine diet become irritable less sex-conscious. Menstruations are more frequent and painful. Carlson says the thyroid

is a specific necessity for development of reproductive glands in males and the lunar cycle in females. Food iodine as available in KELVITA

is necessary for the healthy action of your thyroid.

VITAMINS B and E. Altho KELVITA contains generous amounts of Vitamins A B C and E we are here principally concerned with

Vitamins B and E of which KELVITA is particularly abundant. Vitamin B as in KELVITA is especially needed by children and those

desiring to gain weight, insures appetite for other foods to gain bodily growth was proven by the University of California. is essential

in the mental development of children was proven by Dr. Mauer of University of Chicago. The natural oil in the wheat embryo of KELVITA

aids in overcoming constipation.

'Vitamin E is needed by everyone who do not wish to become impotent (to grow old prematurely) it insures normal development of reproductive

organs prevents sterility. Vitamin E and the food iodine in KELVITA go hand in hand toward this end. Needed by prospective Mothers to

insure normal development of child and to lessen the chances of the Mothers body becoming mineral starved. Dr. Sherman of Columbia

University proved that animals fed a no-vitamin E diet fail to reproduce their kind.

IT'S UP TO YOU MAKE YOUR DECISION TODAY DON'T LET YOUR BODY BECOME A FERTILE FIELD FOR ANY DISEASE. If you eat civilized foods you need KELVITA.

There is no drugs or herbs of any nature in KELVITA. Take it freely every day notice the great change in your health. Be sure your children get

their share. KELVITA is economic health assurance. KNOW THE THRILL OF BEING FULLY ALIVE—THE JOY OF VIBRANT ENERGY.

The writer and his family all get their daily ration of KELVITA and for over four years have not had even a cold. He

challenges anyone his age to compete in any physical contests.

Kelvita possesses no more "magic of nature" than do common foods. The advertising is of the usual false "patent medicine" quackery type apparently intended to deceive the gullible,

the sick, or those with imagined ills. The artifices are clearly evident. Smatterings of facts are intermingled with falsehood

giving the entire copy a semblance of truth. Names of well known authorities are inserted to give confidence. The material

is pseudoscientific. The appeal of sex potency, the dread of its loss, are adeptly used to captivate the morbid.

Advertising such as this is an example of the kind that is causing a growing public demand for federal legislation for

the control of advertising in the interest of public welfare. The Committee on Foods vigorously opposes such deceptive advertising.

SATURDAY, JANUARY 19, 1935

REPORT OF THE FEDERAL FOOD AND DRUG ADMINISTRATION

The recently published report of the Federal Food and Drug Administration, covering its activities during the year ended June 30, 1934, emphasizes the manner in which the administration has carried on its important work despite the limited resources and facilities provided by Congress and in the face of a notoriously deficient federal Food and Drugs Law. Approximately 54,000 samples of foods and drugs were analyzed by the bureau during the year. Nearly 1,100 criminal prosecutions were recommended and 1,729 shipments of adulterated or misbranded products were seized. Several hundred million pounds of foods from foreign sources were inspected, entry was refused to 4,223 proposed importations of foods and drugs. More than 6,000 samples of fruits and vegetables were analyzed for poisonous residues of sprays used as insecticides. Fifty-eight consignments were found to contain "dangerous" quantities and these were seized. This work the Food and Drug Administration considers its most important single activity, indeed, judging from the large number of shipments seized, spray residues must constitute an important menace to the public health, particularly in view of recent studies on chronic poisoning with heavy metals, for instance those that implicate lead intoxication in the etiology of multiple sclerosis.¹ The administration reports that state agencies have been of great assistance in this work. Fortunately the number of effective devices installed by growers to wash the spray residue from the foods has increased, but it is evident from the number of seizures reported that conditions in this respect are far from ideal.

The return of alcoholic beverages brought a number of new problems to an already overburdened administration. Alcoholic candies, still prohibited by law despite the repeal of the eighteenth amendment, were widely distributed, cases of intoxication among school children from the ingestion of these confections were

reported in the newspapers. Nineteen seizures were made and criminal prosecutions were initiated, thus with the aid of local and state authorities this traffic was quickly suppressed. Attention was directed to "products sold as medicinal whisky, but not of United States Pharmacopeial purity, to imitations sold as genuine whisky, to products clearly short in volume, and to products mislabeled as to alcoholic content." About 400 samples were analyzed, none contained ordinary denaturants. Of approximately 250 samples of products represented as medicinal whisky, over two thirds failed to meet the pharmacopeial standards, twenty-nine seizures resulted, and in other cases manufacturers relabeled outstanding stocks. Forty-nine seizures were made of products incorrectly labeled as whisky or as Scotch whisky, for example, mixtures of pomace and raisin brandies, or colored molasses spirits, or Scotch whisky diluted with neutral spirits and colored with caramel. Some products were short in volume or had false and fraudulent therapeutic claims on the labels. In the words of the report, "It is self evident that the present resources of the Food and Drug Administration are wholly insufficient to patrol the entire interstate and import liquor traffic and at the same time meet the other obligations in the way of protecting the purity of the food and drug supply imposed by the federal statute."

Seizures were made of 421 medicinal preparations bearing false and fraudulent therapeutic claims, 232 consignments were made the basis of criminal prosecution. "In the absence of a federal statute applying the same standards of honesty and fair dealing to advertising that now apply to label declarations, manufacturers and distributors of proprietary remedies have an easy method of evading the penalties of the statute by selling their products under truthful labels and continuing their extravagant claims through the medium of advertising."

Only seven cans of anesthetic ether of a total of 1,308 examined were found to be substandard, about 130 of more than 200 samples of other drugs that were analyzed justified prosecution.

A notable section of the report is devoted to the "crystal craze." "The last year or two has witnessed the development of a new type of medicinal humbug in the marketing of almost innumerable brands of so-called mineral crystals, which are essentially laxatives or cathartics and owe their physiological properties to the presence of some well known therapeutic agent, usually sodium sulphate. Medicinal claims of the most extravagant character are made for them. The more adroit manufacturers are careful to restrict such claims to radio and other advertising distributed separately from the interstate package. Where this precaution is taken, action under the Food and Drugs Act is impossible because of lack of jurisdiction. Attention to these products, however, resulted in thirty seizures directed against fourteen products."

¹ The Occurrence of Lead in Cerebrospinal Fluid editorial J. A. M. A. 102:1500 (May 5) 1934. Lead and Multiple Sclerosis *ibid* 102:1852 (June 2) 1934.

It is reassuring that the administration proposes to continue its efforts to amend the Food and Drugs Act. Thus the report says

The fight for effective food and drug legislation is not ended. The months of effort already expended have not been wasted. Constructive suggestions have been developed in the course of the hearings which will undoubtedly improve the chances for the enactment of legislation at the next session of the Congress. Most important, however, is the aroused public interest in the purity of the food and drug supply, a concern which has long been dormant. This interest, once aroused, will unmistakably grow into a united demand for effective legislation which cannot be gainsaid.

Last week THE JOURNAL emphasized the recommendations of the Council on Pharmacy and Chemistry and of the Committee on Foods relative to new food and drug legislation. Some type of control over advertising is a necessity of the times. Foods and drugs of unsatisfactory potency or purity constitute a real public health hazard.

CONSTITUTION AND HEART DISEASE

Attempts to correlate certain body types with disease states are being made with increasing frequency. Granted that such studies are in their infancy and that their significance is not yet fully appreciated, they are nevertheless of much theoretical and possible practical interest. Recently Pearl and Ciocco¹ have investigated the somatologic differences associated with diseases of the heart in white males.

Their study was based on the records of clinical and anthropometric observations made at the Institute for Biologic Research of Johns Hopkins University. For the purposes of the investigation the males (all white) were divided into two groups according to the results of the clinical examinations. In one group were placed those patients who at the time of the examination gave no clinical evidence of cardiac disease, and in the other those who at the time gave clinical manifestations of cardiac disease, mild or grave as the case might be. The total number of males was 245, of whom 133 were "noncardiacs" and 112 were "cardiacs." The basic problem with which the study was concerned was what, if any, significant somatologic differences there are between the cardiacs and noncardiacs of these groups.

Because of the lack of homogeneity in age between the two groups, the final study was confined to those persons whose ages fell between 40 and 69 years. The numbers were thus considerably reduced (eighty-seven cardiacs and fifty noncardiacs) but the relative mean age difference between the groups was much smaller and probably too small to make any appreciable difference in any conclusion regarding somatologic characters. In comparing the two groups on the basis of diagnosed pathologic conditions the cardiacs were characterized as a group by a 100 per cent incidence of heart lesions together with a relatively high incidence

of arteriosclerosis, nephritis and diabetes. The non-cardiac group showed no lesions of the heart or the circulatory system, practically no nephritis or diabetes, but relatively more syphilis and malignancy.

The mean, median, standard deviation, coefficient of variation, minimum observation, maximum observation and range of variation for each of twenty-two somatic variables were directly measured, tabulated and discussed. The two groups were found substantially identical with respect to mean stature, span, head length, head breadth, biacromial breadth, ear length, ear breadth, height at external auditory meatus, height at suprasternal notch, height at lower costal margin, sitting height and trunk length. The cardiac group exhibited means larger than the noncardiac group by amounts certainly or probably of statistical significance with regard to the probable error in the following dimensions: body weight, biiliac breadth, greatest hip breadth, chest depth, head girth, neck girth, chest girth at expiration, at rest and at inspiration, and girth at the umbilicus. The cardiacs tended to be more variable than the noncardiacs both absolutely and relatively in respect to those dimensions for which they had larger means.

The chest expansion index is significantly smaller, on the average, in the cardiacs than in the noncardiacs. The cardiacs as a group tend also more toward dolichocephaly, though the means place both groups in the mesocephalic class in the standard system. There is, however, no statistically significant difference between cardiacs and noncardiacs in respect to their distribution to the three standard somatologic types, asthenic, intermediate and pyknic.

The broad general result that emerges from this study appears to be that a group of white males with definite heart disease of one sort or another is characterized somatologically, on the average, primarily by greater body weight consequent chiefly on greater body girths and breadths, particularly of the trunk and chest as contrasted with a group of white males of substantially the same average stature in which there is no cardiac or circulatory disease. Accompanying this structural difference goes also a significant functional deficiency of the chest as a breathing mechanism. All the evidence points to the conclusion that these characteristics of the cardiac group are not the consequence of true innate constitutional differences in the usual sense of the words but are rather due to accumulation of body fat from relative overeating and lack of physical exercise. This conclusion is supported by much evidence as, for example, the substantially identical distribution as to somatologic types in the two groups. Furthermore, Davenport and Love's data on young cardiacs (draft recruits) show that at such relatively early ages there is no marked somatologic differentiation of cardiacs from noncardiacs. The fact remains that the individuals in the cardiac group belonging to each of the three somatologic types

¹ Pearl Raymond and Ciocco Antonio. Studies on Constitution. 11 Somatological Differences Associated with Diseases of the Heart in White Males. *Human Biology* 6: 650 (Dec.) 1934.

asthenic, intermediate and pyknic tend to the heavier and of greater girth than the individuals of the same type who are noncardiacs

The investigators do not claim, as a result of their observations, that overfatness is a primary or even a significant factor in the cause of heart disease of middle age or of advanced years. Their results do show some association between the two conditions. Studies of constitution in relationship to disease demand a vast material studied under diverse conditions before final conclusions may be drawn.

ABSORPTION AND STORAGE OF VITAMIN A

The circumstances surrounding the discovery of vitamin A emphasized the indispensability of this food factor for normal nutrition. No small part of the investigative effort in the two decades since its discovery has been expended in the detection and estimation of vitamin A in food materials. Many of the puzzling features of the distribution of this factor and its behavior toward chemical manipulation have been partially explained by the recently established relationship between it and the natural pigment carotene. There is convincing evidence that the vitamin A activity of plant materials is due largely to carotene, which, when taken into the body, is transformed to vitamin A, whereas the potency of active sources of animal origin arises largely from the presence of the vitamin itself. Aside from its recognized requirement for maintenance and growth, there exists a close correlation between an adequate supply of vitamin A and the integrity of the epithelial tissues. Widespread metaplasia and infection throughout the body have repeatedly been demonstrated when this food factor is lacking in the food of experimental animals. From the point of view of pathology, therefore, the expansion of knowledge of this essential dietary constituent is justified.

In an effort to extend the knowledge concerning vitamin A, Baumann, Rusing and Steenbock¹ have recently investigated the absorption and storage of this factor. When the colorimetric method of determination was applied to the nonsaponifiable portion of the tissue extracts, it was found in confirmation of other investigators that about 95 per cent of the total body store of vitamin A is found in the liver, the remainder being accounted for by the kidneys and lungs. When the liver contained none, the other organs likewise gave a negative test. The tissues of an animal showing the outward effects of deprivation of this factor were uniformly devoid of it. In the new-born, the store of vitamin A in the liver is small, it decreases for a short time, after which the storage proceeds at a rapid rate. The concentration of this food substance in the livers of the new-born can be increased by augmenting the diet of the mother with added vitamin

A during pregnancy or lactation. That the process of storage of this factor is extremely inefficient was shown by the observation that, when eight times the quantity necessary to cure ophthalmia was fed daily for four weeks, only a faint trace of stored vitamin was found in the liver. Likewise when a large storage had been attained there occurred a progressive loss as time passed.

The proportion of the ingested vitamin A stored in the liver is not great. Using diluted halibut liver oil as the source of the food factor, the Wisconsin group recovered only about 20 per cent in the livers of experimental animals. The speed of absorption, however, was surprisingly great, the larger part of the absorbed vitamin appearing in the liver between the third and the sixth hour after administration. The feces were then examined for vitamin A, the fact that, after a relatively large dose, none of the vitamin was excreted in this way indicates that a large part of the material was destroyed or converted into a nonactive form in the intestine. The study also showed that, in animals previously depleted, more vitamin A was required to bring about storage than if the previous intake had been adequate.

It appears that vitamin A, indispensable for normal function as well as for intact structure, is exposed to many uncertainties under ordinary circumstances of alimentation before it is stored in the body. Normal digestion and absorption of fats is a prerequisite to the utilization of this food factor. Both carotene and vitamin A can be prevented from entering the body by certain otherwise effective therapeutic agents.² Furthermore, the recent studies show that it is easier to maintain those stores than to replenish them. These various observations still further confirm the biochemist in the view that vitamin A continues to merit careful consideration.

Current Comment

SECTION ON SURGERY AT ATLANTIC CITY SESSION

At the Atlantic City session of the American Medical Association, next June, the Section on Surgery, General and Abdominal, hopes to produce a program of rather unusual character, emphasizing physiology and physiologic surgery rather than the technical aspects of the subject. The thesis of the session is the statement by Claude Bernard that "life is contingent upon maintenance of circulation, health upon an equable distribution of an adequate volume of wholesome blood and lymph, the internal environment of the body." Disease represents a disorder of the system for which the correction is sometimes medical, sometimes surgical. Study of the changes that have occurred in the blood and lymph reveals, in most instances, the efficacy of treatment. With this point of view the Executive

¹ Baumann, C. A., Rusing, B. M. and Steenbock, Harry. *J. Biol. Chem.* 107: 705 (Dec.) 1934.

² The Utilization of Vitamin A and Carotene editorial. *J. A. M. A.* 103: 1540 (Nov. 17) 1934.

Committee of the section, including Drs J L Yates, Fred Runkin and Harold Brumm, are developing three sessions pointed toward a physiologic approach to the surgical problem. These sessions include

First session, normal and morbid physiology of blood and lymph formation and distribution. Each presentation, including introduction by American chairman and summaries of medical and surgical aspects, will be limited to ten minutes. An open discussion, limited to five minutes, will follow.

Second session, address by Canadian chairman papers on diagnosis and treatment of diseases primarily due to faulty blood formation and distribution, limited to fifteen minutes and discussion limited to five minutes.

Third session, papers on prevention, diagnosis and treatment of other diseases (exclusive of those of pleurae, lung and central nervous system) with reference if possible to correlated effects on blood formation and distribution, limited to fifteen minutes, discussion to five minutes.

It will be remembered that the Atlantic City session is to be a joint session with the Canadian Medical Association, and that contributors from both countries will be recognized on the program. Those who feel that they have a contribution of merit for any of the sessions here listed may communicate with the secretary of the section,¹ the final date for submission of title and summary being February 1.

Association News

MEDICAL BROADCASTS

Columbia Broadcasting System

The American Medical Association broadcasts on a western network of the Columbia Broadcasting System each Thursday afternoon on the Educational Forum from 4:30 to 4:45, central standard time. The next three broadcasts will be as follows:

January 24	Progress Against Arthritis	Irving S. Cutter, M.D.
January 31	Thirty Six Thousand Deaths	W. W. Bauer, M.D.
February 7	Heart Diseases	W. W. Bauer, M.D.

National Broadcasting Company

The American Medical Association broadcasts under the title "Your Health" on a Blue network of the National Broadcasting Company each Tuesday afternoon from 4 to 4:15, central standard time. The next three broadcasts will be as follows:

January 22	Health in Winter	W. W. Bauer, M.D.
January 29	Organizing for Health	Morris Fishbein, M.D.
February 5	Pipes and a Pump	W. W. Bauer, M.D.

THE ATLANTIC CITY SESSION

Special Exhibits by Various Sections in the Scientific Exhibit

In the Scientific Exhibit at the Atlantic City Session there will be several features sponsored by different sections of the Scientific Assembly.

The Section on Obstetrics, Gynecology and Abdominal Surgery is planning a special exhibit on "The Treatment of Obstetric and Gynecologic Hemorrhage." There will be special demonstrations and motion pictures.

The Section on Pediatrics will present an exhibit symposium on "Acute Infections of the Central Nervous System" with special reference to poliomyelitis, encephalitis and meningitis. This symposium will be composed of a group of exhibits by various individuals, covering the salient points of these diseases.

The Section on Nervous and Mental Diseases will have a special exhibit on "Incipient Nervous and Mental Disorders." It will take up especially the relation of the physician in general practice to such disorders.

The Section on Dermatology and Syphilology will conduct an exhibit symposium on the subject of "Syphilis," composed of a group of exhibits on different phases of the disease.

Persons desiring to take part in the Scientific Exhibit may obtain application blanks from the Director, Scientific Exhibit, American Medical Association, 535 North Dearborn Street, Chicago.

Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION, PUBLIC HEALTH, ETC.)

DELAWARE

Industrial Medical Research Laboratory Dedicated—The Haskell Laboratory of Industrial Toxicology of the E. I. du Pont de Nemours Company, Wilmington, was formally dedicated January 22. The laboratory will be operated by the medical division of the service department of the company to study the possible effect on the health of workers of new chemical products during their manufacture and on the public health. The laboratory, which is said to be the only one of its kind in the United States, has been named in honor of Mr. Harry G. Haskell, a vice president of the du Pont Company, who has long been interested in the development of the company's medical division. It will be under the supervision of Dr. Wolfgang Felix von Oettingen, medical director, who was formerly assistant professor of pharmacology at Western Reserve University School of Medicine, Cleveland. He will have five assistants in addition to other attendants. In addition to offices, the building contains laboratories for biochemistry, pathology and toxicology, with auxiliaries all completely equipped with the latest appliances and facilities. A complete library will be provided for use in studying toxicologic problems in the field of industrial hygiene.

DISTRICT OF COLUMBIA

Medical Bills in Congress—S. 31, introduced by Senator Copeland, New York, proposes to direct the Commission on Licensure to Practice the Healing Art in the District of Columbia to issue a license to practice the healing art to Dr. Chester C. Groff. S. 401, introduced by Senator Copeland, New York, has passed the Senate, proposing to substitute the corporation counsel of the District of Columbia for the United States Attorney for the District of Columbia as a member of the Commission on Licensure to Practice the Healing Art in the District of Columbia, and to put prosecutions and all proceedings under the act in the hands of the corporation counsel instead of the United States attorney.

GEORGIA

New Auditorium for District Meeting—The meeting of the Sixth District Medical Society, December 5, marked the informal opening of a new auditorium sponsored by the Macon Hospital Commission and the Bibb County Medical Society in Macon. The building, once a church, was taken over by the Public Health Board of Bibb County and remodeled. The second floor has been renovated to form the auditorium, with funds provided by the hospital commission and the county medical society. Speakers at the district society meeting included Drs. Charles N. Wasden, Macon, on iodine in the treatment of diseases of the thyroid gland, John M. Sigman, Macon, treatment of acne without scarring, Olin H. Weaver, Macon, ectopic pregnancy, Henry D. Allen Jr., Milledgeville, iron deficiency anemia, and Guy T. Bernard, Augusta, skin cancer.

The exact date and place will be announced later. The American Board of Pediatrics announces that an examination will be held, November 19, in St. Louis.

Prize for Research in Biochemistry—Eli Lilly and Company, Indianapolis, has established under the auspices of the American Chemical Society a research award of \$1,000 and a bronze medal to stimulate research in biologic chemistry by a young man or woman working in a college or university in the United States. Science reports. The nominee for the award must not have passed his thirty-first birthday on April 30 of the year in which the award is made and must have accomplished outstanding research in biologic chemistry. Work in immunology, pharmacology, clinical investigations and experimental therapeutics may not be included in the term biologic chemistry for the purpose of this award.

Medical Bills in Congress—S. Res. 28, introduced by Senator Black, Alabama, and referred to the Senate Committee on Education and Labor, proposes to direct that committee to make a full and complete investigation to determine the best and most effective kind of federal legislation to provide a system of health insurance throughout the United States and to report to the Senate as early as practicable the recommendations outlining the kind of legislation that will most effectively accomplish the purpose. S. 5, introduced by Senator Copeland, New York, and S. 580, introduced by Senator McCarran, Nevada, and referred to the Senate Committee on Commerce, propose to prevent the manufacture, shipment and sale of adulterated or misbranded food, drink, drugs and cosmetics, and to prevent the false advertisement of such articles. S. 142, introduced by Senator Davis, Pennsylvania, proposes to authorize the President to accept radium in an amount not exceeding \$10,000,000 worth, from the Belgian government in payment of the debt owed by that country to the United States. The radium so accepted it is proposed, will be donated to hospitals, medical clinics and medical research organizations in the United States. S. 363 introduced by Senator Capper, Kansas, proposes that for the purposes of promotion, longevity pay and retirement there shall be credited to officers of the Veterinary Corps, and former officers of the Veterinary Corps now on the retired list, all full time service rendered by them as veterinarians in the Quartermaster Department, Cavalry or Field Artillery. H. R. 16 introduced by Representative Fulmer, South Carolina, proposes to provide for federal cooperation with the several states in the care, treatment, education, vocational guidance and placement, and physical rehabilitation of 'persons under the age of 21 years who have some physical defect such as affections of the joints, affections of the bones, disturbances of the neuromuscular mechanism, congenital deformities, static and other acquired deformities that may be corrected or improved by orthopedic surgery or other surgical and medical care.' H. R. 43, introduced by Representative Rudd, New York, proposes to provide that employees of the Postal Service suffering from tuberculous nervous diseases or kindred occupational ailments be hospitalized by the United States without cost to the employee. H. R. 174 introduced by Representative Reece, Tennessee, proposes to provide that any veteran, not dishonorably discharged who is in need of hospitalization, and is unable to defray the expense therefor may be furnished hospitalization in any Veterans' Administration facility within the limitations existing in such facilities, on the payment of a per diem fee in an amount equal to the average cost of hospitalization per patient day at the facility for the previous month. H. R. 197 introduced by Representative Buckbee, Illinois, proposes to prohibit untrue, deceptive or misleading advertising through the use of the mails or in interstate or foreign commerce. H. R. 10 introduced (by request) by Representative Celler

New York, H. R. 2827, introduced by Representative Lundeen, Minnesota and H. R. 2859, introduced by Representative Sabath, Illinois, propose to provide for the establishment of unemployment and social insurance, conferring on the Secretary of Labor the right to provide social insurance for the purpose of paying workers insurance for loss of wages because of part time work, sickness, accident, old age or maternity. H. R. 1425, introduced by Representative Woodruff, Michigan would authorize the withdrawal of alcohol tax free 'for the use of any clinic operated for charity and not for profit, including use in the compounding of bona fide medicines for treatment outside of such clinics of patients thereof, but not for sale.' H. R. 1990, introduced by Representative Bland, Virginia, proposes to provide hospitalization for retired or disabled seamen. H. R. 2000 introduced by Representative Pierce, Oregon proposes to authorize the dissemination of information relating to the prevention of conception, and articles instruments substances, drugs and medicines designed, adapted or intended for the prevention of conception, (1) by any physician legally licensed to practice medicine or by his direction or prescription (2) by any druggist in filling any prescription of a licensed physician, (3) by any medical college legally chartered or (4) by any licensed hospital or clinic, except in any state in which such use is prohibited by the law thereof. H. R. 2018, introduced by Representative Griffin, New York, proposes to provide medals of honor and awards to government employees for distinguished service in science or for voluntary risk of life and health beyond the ordinary risks of duty. H. R. 2027, introduced by Representative Harlan, Ohio, proposes to provide additional compensation to World War veterans for the loss of use of an eye in active service in line of duty. H. R. 2773 introduced by Representative Englebright, California, proposes to authorize the erection of a veterans hospital in the inland region of California. H. R. 2824, introduced by Representative Lundeen, Minnesota proposes to reenact all laws granting medical and hospital treatment, domiciliary care and compensation to veterans that were repealed by the act of March 20, 1933. H. R. 2902 introduced by Representative Welch, California, proposes to extend the benefits of the United States Public Health Service to fishermen, trappers, net tenders and other persons subject to the laws relating to American seamen. H. R. 3024, introduced by Representative Hoepfel, California proposes to provide hospital treatment and domiciliary care to the retired personnel of the armed services.

FOREIGN

About 4,000 deaths were said to have occurred in one district. The dispatch said that fifty physicians were on their way to the island from India.—An epidemic of exanthematous typhus was recently reported throughout Chile. The districts principally affected are near Santiago.

Personal—Dr. Amy M. Fleming, senior assistant in the gynecologic department of the University of Glasgow has been appointed to succeed Dame Louise Mellroy in the University of London chair of obstetrics and gynecology tenable at the London School of Medicine for Women.—Dr. Otto Naegeli, Zurich, Switzerland, was made an honorary member of the American Society of Clinical Pathologists recently.—Dr. Malcolm H. MacKeith, who was appointed dean of the new British Post-Graduate Medical School at Hammersmith a year ago, has been forced to resign because of ill health. The staff of the school has been completed and it is expected that it will be open for teaching purposes about April 1. Applications for the position of dean have been thrown open to the general medical profession.—Sir Henry B. Brackenbury was recently reelected to the General Medical Council for a term of five years representing the general medical practitioners resident in England.—Sir Henry Wellcome was decorated with the Cross of the Legion of Honor of France November 23.—The Copley Medal of the Royal Society of England has been awarded to Prof. John S. Haldane in recognition of his research on human physiology. With the king's approval a royal medal has been awarded to Dr. Edgar Douglas Adrian for his work on the physiology of nerve and its application to the problem of sensation.—Dr. Leslie J. Witts has been appointed professor of medicine and Dr. Geoffrey Hadfield of the University of Bristol, professor of pathology at the University of London tenable at St. Bartholomew's Hospital Medical College.

Physicians Must Broadcast Anonymously

The General Medical Council (the body appointed by the government to control medical education and the conduct of physicians) made a regulation in 1932 that, when in the interest of education or information of the public, it is desirable or necessary that matter concerning medicine or public health should be broadcast, the person broadcasting and his remarks should be approved by a physician nominated for the purpose by the Ministry of Health. This regulation has now been rescinded and the council has decided that physicians must broadcast anonymously that correspondence addressed to them should not be forwarded, and that their anonymity must be strictly observed in connection with any inquiries relevant to them or their talks. Also the Council is to be furnished after the event with names of the broadcasters and the text of their matter. The basis of the Council's action is that anything in the nature of advertising by a physician is strictly forbidden. What he does in broadcasting must not be susceptible of being construed as advertising, whether directly or indirectly, for the purpose of obtaining patients or promoting his own professional advantage."

The Mortgaging of Insurance Practices

A procedure that has sprung up in the north of England, of physicians buying panel practices by mortgaging them to money lenders, has engaged the attention of the Insurance Acts Committee of the British Medical Association. The chairman, Dr. H. G. Dain, has referred to the detrimental effect on the service of a commercial interest in a practice by lay people and to a scheme whereby physicians with little or no capital might obtain under proper auspices loans for the purchase of a practice. In some parts of the north of England it is said to be difficult to purchase a practice from a physician, because the financial corporations get in first and offer cash down. They also circulate newly qualified men, pointing out how easy it is to purchase a practice as they provide the money. The procedure has a bad influence on the efficiency of the service. The financial corporation makes tempting offers to sellers and therefore imposes onerous conditions on buyers who may have difficulty in fulfilling their obligations and resort to canvassing and the easy issue of certificates in order to get patients. On the other hand, it has been suggested that in such cases, when the practice is really owned by the money lender and the physician is in the position of a salaried servant, unethical transgressions are less likely because he is not seriously concerned to enlarge the practice so long as he obtains his salary regularly. The committee is endeavoring to frame a scheme with a medical insurance agency for the purchase of practices whereby, reasonable security being afforded, the whole of the money might be provided under terms not too onerous or likely to commercialize the practice. Young physicians would thus be saved from the speciously attractive propositions of financial corporations.

A Medical Trade Union

The Medical Practitioners' Union is a trade union which was formed in 1915 by physicians who thought that an organization on these lines which have never been adopted by the British Medical Association was desirable. It is a smaller body and has nearly 6,000 members. It has joined forces with the other labor unions. The General Council of the Trades Union Congress has accepted the proposal of the Medical

Practitioners' Union for affiliation. This is the first time that a medical society has been linked up with the Trades Union Congress. In a press interview the secretary of the union stated that the object of this move is mainly to protect members who are engaged by county and municipal authorities. "Where negotiations are needed," he said, "it will give added strength but it must not be taken that this affiliation means the possibility of a strike against the sick. Every union affiliated with the Trades Union Congress is governed by its own rules and that of course, applies to us. It is unthinkable that there should be a strike against people who are ill, nor would anybody expect doctors to take such a step. We are endeavoring to help many members of our union, and to do that we have had to apply wholly as a union." It is one of the objects of the trade unions to be able to declare a general strike, and one actually took place a few years ago but was unsuccessful. The government was equal to the emergency and essential services were maintained by volunteers. It is understood that the application from the Medical Practitioners' Union was accepted without qualification, no specific point being raised on the question of a general strike. The calling out of the physicians in the case of another general strike would be the *reductio ad absurdum* of trade unionism. The majority of the physicians in this country abhor this movement by a section of the profession. It is certainly due to the great increase of state interference in medical practice in recent years, of which the most important manifestation is health insurance of the wage earners. The idea is, as indicated, to confront the state or the local authorities who employ physicians by a powerful organization.

THE POSITION OF THE BRITISH MEDICAL ASSOCIATION

The question has arisen. Can these medical trade unionists retain membership in the British Medical Association, which is opposed to anything that savors of the political? In a press interview the secretary of the Medical Practitioners' Union said that they were not concerned with politics but only with medical politics—a vastly different thing. Both organizations were voluntary bodies and physicians could be members of both, just as they could be members of two golf clubs. He saw no reason why the two bodies should clash. However, Dr. Anderson, medical secretary of the British Medical Association, has expressed a different view in another press interview. He agreed that physicians may still subscribe to membership in both organizations but said: "They must be men of elastic conscience. Personally I could not do it, because I do not believe in the union's methods. In affiliating with the trade unions they are trying to anticipate the political movement in this country. [He evidently refers to a possible victory of the labor party.] The union will alienate the sympathies of a good many of its members by this move. The British Medical Association does not need to be a trade union to fulfil its objects. Nearly 60 per cent of the profession are members of the association and the turn of events does not perturb us in the least."

Radiologic Examination of the Gastro-Intestinal Tract

At the section of radiology of the Royal Society of Medicine, Dr. B. R. Kirklin of the Mayo Clinic, Rochester, Minn., read a paper in which he stated that only by x-rays could the earliest cancerous growths of the alimentary tract be found. Also, certain nonmalignant growths could be found and treated with greater success early than late. Hemorrhage was an urgent indication for radiologic investigation. Peptic ulcer was so often the cause that it might be the only condition considered by the clinician but as he showed by a series of cases, other conditions such as a small growth in the esophagus, might be the cause. Unless radiologic examination was carried out so as to permit direct frontal inspection, small gastric lesions would escape observation. He made a complete study of the

mucosal pattern after the first swallowings of barium. Bleeding from the rectum called for careful examination of the colon. In one case the double contrast method (air insufflation following a barium enema) showed a polypoid growth in the sigmoid, which proved to be adenocarcinoma. In every case of unexplained or idiopathic anemia a radiologic study of the gastro-intestinal tract should be made. In cases of loss of weight without other objective manifestations, radiologic examination should be one of the first tests.

Jan 28 1935

French Orthopedic Congress of 1934

The French Orthopedic Congress of 1934 was held at Paris, October 12, the chief subjects for discussion being the surgical treatment of the funnel-shaped thorax and that of the paralyses due to Little's disease. The first of these two subjects was covered in the paper of Dr. Charles Garmer of Paris. Until recently this deformity had been treated by external measures, i. e., apparatus alone. The paper was based on nine cases observed in the large orthopedic service of Professor Ombredanne. The chief indications for surgical intervention were (a) dyspnea due to the fact that the expansion of the chest during respiration was limited to its upper segment and (b) cardiac symptoms due either to direct compression of the heart or its displacement toward the left with consequent torsion of the vessels.

These pulmonary and cardiac symptoms do not improve with nonoperative treatment in many cases and the lung condition predisposes to the development of tuberculosis. Such children should be operated on before the fifth year. In older children and adults the operation is much more difficult.

The sternum is mobilized in two steps. First the left costal cartilages (the third to the eighth) are resected for a distance of 2 cm. each, and six days later those of the right side. Gentle traction is applied to the sternum and a cast, which is left for two months. The functional results have been far more satisfactory than the morphologic. The mortality in nine cases has been 18 per cent. One can either resect the costal cartilages as just described or divide the sternum longitudinally.

In the discussion, Froehlich of Nancy stated that the indications for operation should be carefully considered. The operative treatment is indicated if there are evidences of serious pulmonary or cardiac lesions, if these cannot be ascribed to other causes than the funnel shaped thorax.

Mathieu reported three cases. In adults, he resects all the costal cartilages except the first and second. There was marked immediate improvement in all of the three cases. Whether this will be permanent, it is impossible to say.

Richard and Dupuis reported two cases. In one the gap in the divided sternum (second method of Ombredanne) was held open by three bone grafts from the tibia. Postoperative respiratory exercise is very important.

Perrot of Geneva also reported two cases, one in a boy of 18 and the other in a boy of 7. The functional symptoms had completely disappeared in both cases.

The second paper on treatment of spastic paralyses (Little's disease and encephalopathies) by Delchef of Brussels and Roudil of Marseilles, reviewed thoroughly the anatomy and the pathophysiology. The only prophylactic measures were to treat a maternal syphilis, to avoid trauma during delivery and, as early as signs of hereditary syphilis appear, to treat this vigorously. After the lesions have developed, the only medical treatment is to administer antisyphilitic preparations. In addition to reeducation, which, when employed alone helps the milder cases, much depends on the stage of the disease. The Stoffel operation is beneficial when there is a spastic condition but is

of no avail when there is muscular retraction. Here only some form of tendon operation, either tenotomy or elongation of the tendon, preferably the latter, is indicated. The location of the spasm is an important consideration. If there is flexion-pronation deformity of the wrist and fingers, only tendon elongation or transplantation or a Stoffel operation is indicated, whereas, if there is an equinus deformity of the foot a tenoplasty is necessary to correct it. In general, the lack of mental development and the tendency to hypertonicity of the choreo-athetotic movements seriously complicate the problem of treatment. One must never forget that there is a tendency to spontaneous amelioration of the disease. Each case requires individual study.

Hygiene of Natatoriums at Seaside Resorts

At the recent hygiene congress in Paris, des Essarts called attention to the unhygienic conditions existing in the swimming pools containing water pumped directly from the ocean which now exist at some of the large seaside resorts in France. The water in these pools is not only polluted by sewage, which is discharged near the source of supply for the pools, but is also contaminated by the thousands of persons who prefer to use the pools instead of bathing in the adjacent ocean. No effort is made to change the sea water in the pools at frequent intervals and no disinfectants are employed. Hence the water acts like a culture medium especially for the colon bacillus. This explains why one so often sees individuals who have patronized the pools afflicted with conjunctivitis, otitis, gastro-enteric syndromes, typhoid dysentery and various skin diseases.

A plea was made for more rigid control of this innovation at seaside resorts. The water ought to be taken at a point where there is no likelihood of contamination, and chlorination of the water in the pools must be insisted on.

Professor Faure Retires from Hospital Service

Jean-Louis Faure, professor of gynecology at the Paris Medical School, was presented with a medal, November 18, by a large number of colleagues, friends and former patients. This event marked his retirement from many years of service at the Broca Hospital. He is one of the leaders of abdominal surgery in France, and his contributions to gynecology have made the name of Faure known all over the world. In response to many addresses by leaders of the literary and scientific world, Professor Faure stated that he had lived during the epoch of development of the technic of abdominal surgery. The coming generations will never see a more glorious period of the evolution of surgery. Perhaps surgery will be partly replaced by radiotherapy and other measures in the future. There is a tendency at present to place too much reliance on laboratory work and to neglect somewhat the clinical side. The patient should be spared from too many laboratory tests, some of which are superfluous.

Effect of High Temperatures on the Testis

An experimental study of why the testis fails to develop when retained within the abdomen, as observed in cases of experimental cryptorchidism, was reported before the Biologic Society, October 20, by Jolly and Lieure. They do not agree with the theory of Moore that the scrotum is a regulator of temperature and that, as his experiments show, the testes fail to develop when placed in the abdominal cavity, where the temperature is higher. These authors employed guinea pigs (from 3 to 4 months old) the testes of which had fully matured. The testes were exposed for periods varying from ten minutes to one hour in water at a temperature ranging from 40 to 48 C. The testes were examined microscopically from fifteen to thirty-five days after such exposures. No effects were observed at temperatures from 40 to 43 C and only slight changes up to 46 C. When a higher temperature was reached, from 46 to

48 C, marked but not diffuse effects were noted. They do not believe that the intra-abdominal temperatures in experimental animals ever rise high enough to affect the development to maturity of the testis, so that one must look elsewhere for a cause to explain the nondevelopment of the testis in cryptorchidism, at least so far as experimental study is concerned

Treatment of Diphtheria

At a November meeting here the treatment of diphtheria was discussed by some of the leading clinicians and bacteriologists of Paris

Louis Martin, director of the Pasteur Institute, made an appeal for the use of antitoxin at the earliest possible moment, and not to wait for the appearance of false membranes. Intravenous injection acts more rapidly than intramuscular, and the latter more rapidly than subcutaneous. The opinion was unanimous as to the size of the doses, i. e., not more than 200 cc (50,000 units) altogether for a child of 10, 80 cc. is given the first day, 60 cc the second and 40 cc the third.

Debre did not believe that the antitoxin had lost its merited reputation, but it failed to cure malignant cases because employed too late. The physician should not wait for laboratory reports before using the antitoxin. These reports either arrive too late or may be wrong, not showing the specific bacilli when the disease is already present or revealing the presence of short bacilli, so that valuable time is lost. The clinical examination should be the attending physician's guide. Local applications are useless. When a child who has been vaccinated against diphtheria shows evidences of the disease, the antitoxin should be administered the same as though no vaccination had been performed. There are a small number of children who cannot be immunized by vaccination.

Marfan and Debré did not think that antitoxin was of any avail in paralysis, but Lereboullet and Martin did not agree with this view.

Nov 12, 1934

The Congress of German Pediatricians

The German Society of Pediatrics held a congress in Brunswick to commemorate its fiftieth anniversary. The chairman, Professor Stolte of Breslau brought attention in his speech to the progress made in pediatrics, in that it has been recognized as a specialty by the state. About the turn of the century in Germany 19 per cent of all children died during the first year of life, whereas in 1933 only 8 per cent died. In the large cities the difference was even more striking, in Breslau the rate of infant mortality decreased from 29 to 8 per cent within the same period.

Kleinschmidt of Cologne spoke on localization of bacteria in the intestine of new-born children. Spore-forming bacilli appear frequently in meconium and regularly in melena stools. Thanks to progress made in research on anaerobic cultures, it was found that in almost all children the anaerobes were found by the third day as precursors of *Bacteroides bifidus*. Next to already well known micro-organisms, the anaerobe *Bacterium muniticus*, which had not been described before, assumes the main role. It appears in the bacteriologic pictures in different forms. In the feces of the new-born the gas bacillus does not have the importance once attributed to it but in melena it is found frequently and in large numbers.

Investigations of the blood iodine of rachitic nurslings made by Fasold of Göttingen showed normal results. Therefore the thyroid gland cannot have a very considerable influence in the pathogenesis of this disease. The iodine content is not even slightly influenced by the addition of vitamin B. In fact, it diminished on the addition of vitamin A. In experimental scurvy of the guinea-pig, a lack of vitamin C was accompanied

by a notable rise in the iodine content, followed by a marked retrogression.

Jochims of Kiel tested the biologic effect of isolated long ultraviolet rays on 160 rats, aged 6 weeks, under healthy living conditions and an unlimited amount of food containing salt and all the vitamins necessary to growth. When the cadmium lamp was used, the short ultraviolet rays—the anti-rachitic and the erythema producing rays—were held back below 315 microns. In direct irradiation of animals, the short waves had no influence. If irradiations are administered to the animals every two days for thirty minutes, they will be severely burned. If food and animals are mutually irradiated, the animals are soon exhausted. This effect is missing if a filter is not used, that is, if irradiation with polychromatic ultraviolet rays is administered. If the animals are given food with an optimal vitamin content and are irradiated for ten minutes with long ultraviolet rays, they regularly grow stronger than the control animals. This is not present if irradiation is administered with all the polychromatic ultraviolet rays. The sort of growth promoting substance is still a question none of the well known vitamins come into consideration. According to this, an isolated long wave section of the ultraviolet rays produces biologic effects which may not be suspected in mixed ultraviolet rays.

In children presenting general convulsions due to spasmophilia, Stolte observed a strikingly high rest nitrogen value 97, 63 and 48.3 mg per hundred cubic centimeters, while two other children presenting manifest spasmophilia but no convulsions showed only 37.8 mg per hundred cubic centimeters rest nitrogen. The convulsions, however, may not have conditioned the rise in rest nitrogen, for the highest value established after epileptic convulsions of long duration amounted to from 42.3 to 44.3 mg per hundred cubic centimeters rest nitrogen. If these observations really hold true, a possibility of explaining these special manifestations of spasmophilia presents itself. Since in the past shifts in the mineral metabolism had to be taken into account in this disease, the increase in nitrogen containing bodies is of interest. Kleinschmidt of Leipzig dealt with investigations on creatine metabolism in health children and in children having muscular diseases. In children as contrasted with adults a creatinuria is said to be physiologically more in evidence. Kleinschmidt, however, clearly demonstrated that a healthy child whose diet contains no animal albumin does not excrete creatine. Kleinschmidt found creatine in the urine only in the case of muscular diseases. The highest amount of creatine was found in progressive muscular dystrophy of Erb. The creatine metabolism peculiarities of this disease are said to be of differential diagnostic importance, nevertheless Kleinschmidt was able to show that, at most, conclusions may be drawn from the amount of creatine spontaneously excreted—not, however, from the glycocholic or creatine tolerance nor from the excretion of creatine—which indicate whether the dystrophy of Erb or another muscular disease is present. Kleinschmidt was able to determine the characteristic rise in creatine excretion in Erb's dystrophy after glycocholic tolerance also in a large number of healthy children. The results obtained in adults with glycocholic in progressive muscular dystrophy of Erb were not corroborated by those in children.

K. H. Bauer of Breslau spoke on congenital surgical diseases and malformations in the light of heredity. The gene is no hypothetical concept but a highly effective chemical physical entity. Even if its real nature is still unknown, the knowledge of its effect is already widespread. Chondrodystrophy and osteogenesis imperfecta serve as examples of how universal the effects of genes may be. In chondrodystrophic dwarfism it is not only a question of an epiphyseal growth disturbance but also of disturbances of the ossification center of the subchondral cartilaginous growth and of joint forma-

tion Each bone of the entire bone system had become specifically chondrodystrophic. The influence of internal secretions is contradicted by the cases of unilateral chondrodystrophy. The effects of a single gene are even more strikingly illustrated in a case of osteogenesis imperfecta. Here it is not only a question of a disease of the bone system with insufficient formation of the bony substance and predisposition to fractures, as is observed in severe cases by the involvement of other derivatives of mesenchymal tissue. Frequently effects traced to genes may be demonstrated in hereditary malformations, apparently circumscribed locally. A white forelock is, for example, frequently only a symptom of human spottedness, having short hands is only a stigma resulting from having short bones, in hereditary patellar luxation, numerous other joint disturbances are found. The so called hereditary clavicular defect especially demonstrates that such a local malformation is often only a symptom of universal constitutional anomalies. The fundamental importance of such clinical evidence pertaining to a striking genetic effect lies in the fact that its demonstration always permits binding conclusions to be drawn about corresponding normal genes.

Ibrahim of Jena discussed the importance of the diseased anlage in diseases of the nervous system of children. Alcohol, x-rays and radium rays are considered the primary damaging agents. Little definite information is available on the importance of chemical contraceptives. Whether syphilis in the form of parasymphilitic trauma can produce any nuclear damage must be determined by further observation. Fetal trauma in the form of roentgen fetal microcephalia with ocular malformations has become well known. Indirect fetal damages due to rays seem to occur on distant organs of the pregnant woman. Anomalies of the amniotic membranes and of the secretion of amniotic fluid may be called changes in nidation. In the relation of heredity to feeble-mindedness it is not easy to differentiate between endogenous and exogenous forms on the basis of clinical investigation. Recessive hereditary influences may be recognized in mongolian idiocy, but heredity alone does not explain all the known causal influences whereas the nidation theory is in harmony with all known influences. Hereditary influences are assumed in polyomyelitis here structure analyses are made of biologic heredity. Hereditary influences have been found in chorea minor and in spasmodic convulsions of infancy. Neuropathic disturbances may be produced by unfavorable environmental influences but hereditary influences are basic.

Kreuz of Berlin spoke on the special classification of typical deformities in the field of racial hygiene. There is no anatomic difference between hereditary clubfoot and that acquired within the uterus. Just as in congenital luxation of the hip, in clubfoot appropriate early treatment is extremely important because the ability of the child organism to restore the bone to complete usage diminishes with increasing age. The incidence of cure from the functional and anatomic point of view is high in cases treated early enough.

Orel of Vienna tested the influence of blood relationship of parents on children. He studied 686 children born in 305 Viennese marriages occurring during the years 1901-1902-1913 and contracted between persons related to the third or fourth degree. Although the material may be regarded as a consecutive series, it is selected, only the Aryan population was examined. The few unfavorable results found may be explained by the coincidence of recessive, morbid hereditary Anlagen. That detrimental results were produced by inbreeding could be proved no more than the theoretically correct belief that higher types may be cultivated through the joining of valuable recessive hereditary Anlagen.

W. Lehmann of Berlin-Dahlem presented a detailed report on examinations for heredity in rachitic twins. Heretofore

there has been only one statistical report in this subject. Examinations of rachitic changes were made on ninety-five pairs of twins (forty monozygotic—thus hereditarily identical, and fifty-five dissimilar pairs, of which thirty-seven belonged to the same sex and eighteen to both sexes). All were children from 3 to 6 years of age. The results are given in the table.

Heredity in Rachitic Twins

	Rachitic Behavior	
	Same	Different
In 40 identical pairs	34 times=85 per cent	6 times=15 per cent
In 55 dissimilar pairs	15 times=27.3 per cent	40 times=72.7 per cent

The results show that identical twins suffer more frequently in the same way from rickets than dissimilar twins. Since this difference may not be explained by environmental conditions, it should be accepted from these examinations that the hereditary Anlage plays an important part in the etiology of rickets.

A Temporary Hospital Dictator

The revolution in Catalonia last October was organized and carried out by the local authorities of the Catalonian provinces, who spent the money appropriated for the public health of the provinces in preparing for the revolution, leaving the hospitals to be supported by charity. When the revolution broke out, the socialistic miners took Oviedo, the capital of Asturias, where they established their headquarters. The general hospital of Oviedo, the foremost hospital in Asturias, was placed in charge of the nurse Elias, a fanatic socialistic leader and also a tippler, who ordered the physicians of the hospital under arrest. Elias wanted the nuns to dress in modern nursing gowns if they were to continue nursing patients but the nuns would not change their clothing so he improvised a group of nurses with girls from the red light district. The water supply and electric light had been shut off the windows were closed by mattresses, and asepsis and sterilization in operating rooms were impossible. Operations were performed under these conditions on 250 seriously wounded men and of course a high rate of mortality resulted. This fact angered Elias, who summoned the physicians and told them "The fact that gangrene has taken so many victims in the ranks of the socialists and not in the ranks of the soldiers of the government proves that you are against the revolution, if today and tomorrow none of the wounded soldiers of the government die from gangrene I will have you shot." But the dictatorship lasted no longer and some hours later the republic triumphed. Elias died in the last battle. The socialists set fire to fifty buildings and blew up the institute and the University of Oviedo. In the city of Mieres the physicians, who were forced to work constantly from the fifth to the nineteenth of October, were treated as prisoners. Prescriptions could not be filled unless they were approved by a member of the revolutionary committee. The sale of food was supervised by the revolutionary committee, who gave a daily allowance to physicians and their families amounting to one peseta (about ten cents) for every person in the family. The physicians were in misery and their homes were either plundered or burned. The revolution was not justified by poverty, for the socialist miners earn the best wages for workers in Spain. They acted under poor advice.

Difficulties in Spanish Universities

In some universities of Spain, students have formed into groups under the name of university federations. The groups

consist of students of conflicting opinions, those supporting the government and those supporting the revolution. These groups have caused disturbances in the universities. Recently in the University of Madrid one of these controversies resulted in a fight during which four students were wounded, three of them gravely. In the University of Barcelona, Catalan was accepted as the official language. This caused discontent among many Spanish speaking students from South America, who decided to leave the university. When the Italians learned of this discontent, they invited the South Americans to Italy, offering them reductions in the fare of railroads and street cars. More than 200 students went from Barcelona to Genoa.

Ramón y Cajal

Dr. Santiago Ramón y Cajal, the famous Spanish histologist and anatomist, who died recently, was the author, among other works, of the *Manual de histología y de técnica micrográfica*, *Manual de anatomía patológica general*, *Histología*, *Textura del sistema nervioso del hombre y de los vertebrados* (three volumes) and *Trabajos de laboratorio* (twenty-eight volumes). Cajal was a professor of anatomy in the Universities of Barcelona, Zaragoza, Valencia and Madrid and later was head of the Institute Cajal, where scientists from all over the world came to learn his methods. When a statue of Cajal was unveiled in Zaragoza he declined the invitation to attend the ceremonies on account of poor health but really on account of his modesty. Shortly after the Spanish-American War he was received in the United States with great cordiality. He left 25,000 pesetas (about \$2,500) to help educate selected students. The medical society *Colegio de Médicos* of Madrid is organizing the establishment of a school in the city of Petella de Aragón which will be named after Cajal. His burial was a national manifestation of honor to him and of sorrow caused by his death.

ROME

(From Our Regular Correspondent)

Nov. 15, 1934

Congress of Medical Radiology

The eleventh National Congress of Medical Radiology was recently held at Perugia with Dr. Eugenio Milani as president and an attendance of about 400 radiologists and a large number of physicians. The first speaker was Dr. Lapenna of Belluno, who discussed roentgenology of the intervertebral disk, dislocation of the disk and also Schmorl cartilaginous nodules. He classified vertebral diseases into two large groups according to their cause, either extrinsic or intrinsic. The first group includes spondylitis and spondylo-arthritis, which attack the cartilages and the disk, the vertebral body or the ligaments. The second group includes spondylosis and spondylo-arthrosis. The so-called Kummell's spondylitis cannot be considered as a nosologic entity but rather as the terminal stage of an undiagnosed and latent fracture.

Dr. Palmieri of Bologna spoke on radiotherapy of the encephalon. He enumerated the neuropathologic conditions in which roentgen therapy is indicated and discussed the therapeutic action of roentgen irradiations, especially regulation of the interchange of cerebrospinal fluid under irradiations in internal hydrocephalus. In this connection the author refuted Marburg and Igaltzer's interpretations. He stated that roentgen treatment in encephalic tumors sometimes fails by itself to destroy the tumor but it is of value if associated with surgery. Surgery is the treatment of choice in the syndromes of intracranial hypertension and it is also advisable to resort to it in acromegalic syndromes. The collaboration between roentgenologists, neuropathologists and neurosurgeons is essential for the interest of the patient and also with the aim of clarifying many problems, even those of a theoretical nature.

Dr. del Buono of Bari spoke on roentgen therapy of the spinal cord and the peripheral nerves. Roentgen therapy is indicated in nonsuppurative acute neuraxitis of the spinal cord, in neuralgia of a certain inflammatory origin in syringomyelic gliosis, and in medullary and juxtamedullary tumors. The speaker pointed out the satisfactory results of roentgen treatment in acute anterior poliomyelitis in children, in chronic and acute poliomyelitis in adults and in other forms of poliomyelitis. It is now admitted that the direct action of the rays on the inflammatory cells, which constitute the infiltration, is explained by a double effect of the rays, causing destruction of labile cells and checking the proliferation of histiocytes of the connective tissue. In the treatment of syringomyelic gliosis, the pathogenesis of which is now related to spongioblastosis, the action of the roentgen rays seems to depend on the particular radiosensitivity of the residual immature spongioblasts in the spinal cord. After roentgen irradiations of medullary and juxtamedullary tumors, the beneficial action of the rays can manifest itself by the modifications of the cerebrospinal fluid, such as disappearance of inflammatory pleocytosis and of xanthochromia and destruction of neoplastic cells, which are sometimes present in the cerebrospinal fluid. The satisfactory results of roentgen therapy in neoplastic inflammatory diseases of the spinal cord and of the peripheral nerves have been emphasized during the last few years because of the large number of cases observed.

Dr. Guarini of Naples spoke on roentgen treatment of the sympatheticus. He stated that the roentgen irradiations have both an important action on the sympathetic nervous system and definite indications in certain diseases. Michelazzi's studies on the rich innervation of veins, showing ganglions in the adventitia of the pulmonary vessels, led one to suppose that the action depends on the effects of the irradiations on the ends of the sympathetic and other nerves.

Dr. Benassi of Parma spoke on new methods of visualization of various cavities and organs after the administration of contrast mediums. He focused his discussion on the importance of hepatolienography by colloidal thorium dioxide as a contrast medium, and on the new methods of radiologic visualization of arteries and on the method of impregnation of the mucosae with contrast mediums. Lymphography, perineurophalography, amniography and placentography may yet be considered in the experimental stage and probably will not have any clinical application of importance. Hepatolienography with colloidal thorium dioxide is harmless. Neither immediate nor late untoward results were observed by the speaker in more than a hundred cases followed for about three years. Hepatolienography is indicated when it is necessary to find out the volume, shape and position of the liver and the spleen. In the diagnosis of diseases of the digestive tract the examination of the colon by the so-called impregnation of the mucosa by flocculation of colloids of thorium is of importance. The speaker closed by saying that colloids of thorium are better adapted than all the other opaque fluids for the visualization of organic cavities, either normal or in pathologic conditions.

Dr. Durante Is Dead

Dr. Francesco Durante, a senator and surgeon emeritus of the surgical clinic of Rome, died recently. He was the first surgeon to perform, in Italy, the suture of arteries and to undertake operations on the nervous system, especially on tumors of the frontal lobes. He originated a classic technique for craniotomy which was the basis for several modified techniques. He established the theory of the embryonic origin of tumors and published a description of it one year before Cohnheim. He was the founder of the large school of Italian surgery, having directed the surgical clinic of Rome for forty-five years. It is at this clinic that all the professors of Italian universities have studied.

Marriages

EDDIE HOUSTON THOMASON, Olanita, S. C., to Miss Kate Goodwin Odiorne of Manning, Dec 20, 1934

EMIL S. GOODYEAR, Kingston, N. Y., to Miss Mary Clare Archibald of Nashville, Tenn., Dec 21, 1934

FRANK DANA WEEKS, Ashland, Wis., to Miss Frances Mary Clark in Stockdale, Nov 30, 1934

MALCOLM E. MILLER, Ashland, Ohio, to Miss Marian Homewood of Sullivan, Dec 25, 1934

JAMES SLOAN ALTMAN, Pittsfield, Ill., to Miss Florence Mildred Clevin, June 5, 1934

HUGH VICTOR DU BOIS to Mrs F. M. Latham, both of Athens, Tenn., Dec 4, 1934

PAUL PADGET, Baltimore, to Miss Dorcas Hager of Vergennes, Vt., Nov 30, 1934

FRANK A. DONALDSON, Long Island, N. Y., to Miss Agnes Hunt, in November 1934

ELLIS E. BAKER to Miss Opal Mankin, both of Gillette, Wyo., Dec 25, 1934

GEORGE CRILE JR to Miss Jane Halle, both of Cleveland, Dec. 5, 1934

Deaths

E. Rodney Fiske, New York, New York Homeopathic Medical College and Hospital, 1895 associate professor of medicine at his alma mater fellow of the American College of Physicians, associate attending physician to the Flower Hospital, consultant to the Yonkers (N. Y.) General Hospital, Brooklyn, Nursery and Infants Hospital and the Huntington (N. Y.) Hospital and chief of the department of medicine, Carson C. Peck Memorial Hospital, Brooklyn, aged 61, died, Dec. 19, 1934, of Hodgkin's disease

William Kuykendall ☉ Eugene, Ore., Medical College of the Pacific, San Francisco, 1878, Member of the House of Delegates of the American Medical Association, 1926-1931 past president and formerly councilor of the fourth district of the Oregon State Medical Society, formerly member of the state legislature, fellow of the American College of Surgeons, on the staff of the Eugene Hospital, aged 79, died, Dec 7, 1934

Curtis Herman Jennings ☉ Fitchburg, Mass. Baltimore University School of Medicine, 1902 member of the American Roentgen Ray Society, the New England Roentgen Ray Society and the Radiological Society of North America, veteran of the Spanish American and World wars on the staffs of the Burbank Hospital, Fitchburg, and the Elliott Community Hospital, Keene, N. H. aged 58, died, Dec. 31, 1934

Frank Alexander Hughes ☉ Lieut. Commander, U. S. Navy, retired Lexington, Ky., Medical College of Virginia, Richmond 1906, served during the World War entered the navy in 1921 and retired in 1932 for incapacity resulting from an incident of service, part time otorhinolaryngologist to the University Health Service, University of Kentucky, aged 51, died Dec. 23 1934, of cerebral hemorrhage

Herbert Spencer Abel, Providence, R. I., Cornell University Medical College, New York, 1929 member of the Rhode Island Medical Society, on the staffs of the Beth Israel Hospital, Boston, the Charles V. Chapin Hospital, Rhode Island Hospital and the Miriam Hospital Providence aged 31, died Dec. 3 1934 in the Memorial Hospital, Pawtucket, of acute rheumatic fever and acute endocarditis

Peter Alfred Bendixen ☉ Davenport Iowa, Rush Medical College, Chicago 1905 member of the Western Surgical Association fellow of the American College of Surgeons, past president of the Scott County Medical Society, surgeon to St. Luke's Hospital and the Mercy Hospital, aged 52 died Dec. 30, 1934 at a hunting lodge near Beardstown, Ill., of coronary thrombosis

Daniel Edward Sevier, Asheville, N. C. Jefferson Medical College of Philadelphia 1895, member of the Medical Society of the State of North Carolina past president of the Buncombe County Medical Society for many years health officer of Asheville formerly county health officer and county coroner, aged 66, died Dec. 4 1934, of coronary occlusion.

Lowell Lorrimer Youngquist, Marquette Mich. University of Michigan Medical School, Ann Arbor, 1916 member

of the Michigan State Medical Society, served during the World War, physician to the Hospital of State House of Correction and Branch Prison, formerly city health officer, aged 46, died recently, of cerebral hemorrhage

Cleaves Bennett ☉ Champaign, Ill., College of Physicians and Surgeons of Chicago, 1896, past president and secretary of the Champaign County Medical Society, formerly councilor of the eighth district of the Illinois State Medical Society, aged 64, on the staff of the Burnham City Hospital, where he died, Dec 22, 1934, of coronary thrombosis

James Anthony Halpin ☉ Medical Inspector, Commander, M. C. U. S. Navy, Chelsea Mass. Georgetown University School of Medicine, Washington, D. C., 1912, entered the navy in 1917, served during the World War, aged 44, chief of the medical service at the U. S. Naval Hospital, where he died, Dec 11, 1934, of chronic nephritis

Clarence Walter Halliday, Detroit, Harvard University Medical School, Boston, 1920, fellow of the American College of Surgeons surgeon to the Evangelical Deaconess Hospital, junior pathologist to the Harper Hospital, on the staff of the Cottage Hospital Grosse Pointe, Mich., aged 41, died Dec 17, 1934 of chronic myocarditis

Francis Huber ☉ New York, College of Physicians and Surgeons, Medical Department of Columbia College, New York, 1877 professor of clinical medicine at his alma mater, consulting physician to the Gouverneur Hospital and consultant in pediatrics, Jewish and Beth Moses Hospitals, aged 80, died, Dec. 26, 1934, of heart disease

Leland Howard Poore, Crescent Lake, Me., Medical School of Maine Portland, 1893, member of the Maine Medical Association formerly member of the state legislature aged 67, died, Nov 29, 1934 in the Central Maine General Hospital, Lewiston, of uremia, diabetes mellitus and arteriosclerosis

Samuel William Weinberg, Louisville, Ky., Hospital College of Medicine, Louisville, 1904 clinical instructor in otology, rhinology and laryngology, University of Louisville School of Medicine on the staff of the Jewish Hospital, aged 56, died, Nov 21, 1934, of heart disease

Thomas N. Millikin, Wilmington, Del. University of Pennsylvania School of Medicine, Philadelphia, 1893 member of the Medical Society of Delaware, also a druggist, on the staff of the Wilmington General Hospital, aged 72, died, Nov 24 1934, of heart disease

Albert E. Frey, Newark, N. J. College of Physicians and Surgeons, Medical Department of Columbia College, New York, 1888, aged 70, died, Dec. 27, 1934 in the Elizabeth (N. J.) General Hospital, of pneumonia following injuries received in an automobile accident

Samuel Ewer Simmons, Berkeley, Calif. Harvard University Medical School, Boston 1899 member of the California Medical Association, served during the World War aged 60, died, Nov. 21, 1934, in the Alta Bates Hospital, of carcinoma of the lung

August C. Borchardt, New London, Wis., Milwaukee Medical College, 1905, served during the World War, for seventeen years local health officer, aged 62 medical superintendent of the Memorial Hospital, where he died, Dec 16 1934 of angina pectoris

David Robinson ☉ New York. Medizinische Fakultät der Albertus-Universität, Königsberg, Prussia, 1887 chief consultant emeritus to the Beth Israel Hospital, consultant to the Montefiore Hospital, aged 71, died, Dec 6, 1934, of coronary thrombosis

Max B. Gomberg, Providence R. I., University of Pennsylvania School of Medicine, Philadelphia, 1895, on the staff of the Miriam Hospital aged 60, died Dec 12, 1934, in the Rhode Island Hospital, of coronary occlusion and lobar pneumonia

William Joseph Herrick, Ottumwa Iowa Keokuk Medical College 1895 member of the Iowa State Medical Society past president of the Wapello County Medical Society aged 67, on the staff of St. Joseph's Hospital, where he died, Dec 12, 1934

Antone Byron Jensen ☉ Menasha, Wis., College of Physicians and Surgeons of Chicago School of Medicine of the University of Illinois 1903 on the staff of the Theda Clark Hospital Neenah, aged 55 died, Dec 14 1934, of heart disease.

Eugene Moore Fowler ☉ Dallas, Texas, Southern Medical College Atlanta, 1885, fellow of the American College of Surgeons on the staffs of the Methodist Hospital and Emergency Hospital, aged 70 died, Dec. 27, 1934, of coronary occlusion.

Charles Austin Lester, Peoria, Ill., Hospital College of Medicine, Louisville, Ky., 1897, served during the World War, aged 60, died, Dec 9, 1934, in the Veterans' Administration Facility, Hines, of arteriosclerosis and valvular heart disease

Louis David Henn, North Plainfield, N. J., New York University Medical College, 1898, member of the Medical Society of New Jersey, aged 59, died, Dec 12, 1934, in the Muhlenberg Hospital, Plainfield, of chronic endocarditis

Orson Ruez Crooks, Kansas City, Mo. Kansas City Medical College, 1897 member of the Associated Anesthetists of the United States and Canada, aged 64, died, Dec 13, 1934 of coronary thrombosis and arteriosclerosis

Harriett Belle Jennings Wagner, Victorville, Calif., College of Physicians and Surgeons of Chicago, School of Medicine of the University of Illinois, 1903, aged 67, died, Nov 25, 1934, in Etiwanda, of skull fracture

Elisha Whitten Tinsley, Montgomery City, Mo. Hospital College of Medicine Louisville, 1889, member of the Missouri State Medical Association aged 68 died Nov 28 1934, in Mexico of carcinoma of the pancreas

Philo Everett Jones Portland Ore. Medical College of Ohio Cincinnati, 1870, past president of the Utah State Medical Association aged 86, died Nov 22, 1934, of prostatic obstruction and purulent bronchitis

Thomas Hugh Tuten, Alameda, S. C. Medical College of the State of South Carolina, Charleston 1900 bank president aged 59 died, Nov 21 1934, in the Riverside Hospital Charleston, of cirrhosis of the liver

Fred Russell Dame, Athol Mass. Baltimore Medical College 1897 member of the Massachusetts Medical Society aged 62 died Dec 21 1934 in Orange, of skull fracture received in an automobile accident

Frank Roy Loope, Seattle College of Physicians and Surgeons of Chicago, School of Medicine of the University of Illinois, 1901 aged 60, died Nov 7, 1934, of coronary thrombosis and arthritis deformans

Owen Alonzo Smith, Farmington Mo. Washington University School of Medicine, St. Louis 1892 member of the Missouri State Medical Association, aged 66 died Dec 2 1934 of carcinoma of the stomach

Lemuel Temple Waters, Savannah Ga. University of Georgia Medical Department Augusta 1914 member of the Medical Association of Georgia, aged 45 died Nov 27, 1934, of coronary thrombosis

John B. Walkinshaw, Wellsburg W. Va. Western Reserve University Medical Department Cleveland 1883 formerly county coroner, aged 74 died Nov 14, 1934, of chronic myocarditis

Percy Eugene Hofmann, Fargo, N. D. Barnes Medical College, St. Louis 1906, member of the North Dakota State Medical Association, aged 56, died suddenly Dec 18, 1934 of heart disease

John S. Allen, Keithsburg Ill. Hahnemann Medical College and Hospital, Chicago 1877, for many years bank president and president of the board of education, aged 83 died Dec. 15, 1934

Nathaniel Hibbard, Danielson Conn. Harvard University Medical School, Boston, 1882, member of the Connecticut State Medical Society, aged 79, died Nov 28, 1934, of chronic myocarditis

Ulysses Samuel Wharton Altoona, Pa. Howard University College of Medicine, Washington D. C. 1913, on the staff of the Altoona Hospital, aged 49, died, Dec 2 1934, of heart disease

Joseph Grant Yocum Middletown N. Y. Columbia University College of Physicians and Surgeons New York 1901 served during the World War, aged 57 died, Dec 19 1934 of pneumonia

Michael Thomas Naughton, Chicago College of Physicians and Surgeons of Chicago 1894 aged 67 died Dec 12 1934, in the Veterans' Administration Facility, Hines Ill., of nephritis

Jacob A. Poppen, Otsego Mich. Northwestern University Medical School, Chicago 1921, aged 42, died Dec 17 1934 in the Bronson Methodist Hospital, Kalamazoo of diabetes mellitus

John Charles Whitacre, Memphis Tenn. State University of Iowa College of Medicine, Iowa City, 1897 aged 64, died, Nov 15, 1934, of a malignant tumor of the gastro-intestinal tract

Herbert Drew Snyder, Little Rock, Ark., Atlanta Medical College, 1916, served during the World War, on the staff of the State Hospital, aged 41, died, Dec 9, 1934, of heart disease

J. Louis C. Perrilliat, New Orleans, Tulane University of Louisiana Medical Department, New Orleans, 1899, aged 59, died in December 1934, of bronchopneumonia and septicemia.

Walter Pleasant Wilson, Madison, N. C., North Carolina Medical College, Charlotte, 1908 aged 56, died Dec 12, 1934, in St. Leo's Hospital, Greensboro, of bronchopneumonia

John Allen Whipple, Peoria, Ill. National Medical College, Chicago 1895 also a dentist and a lawyer, aged 79, died Nov 22, 1934, in the Proctor Hospital of acute nephritis

Alexander J. Schweichler, Milwaukee, Medizinische Fakultät der Friedrich-Wilhelms-Universität, Berlin, Prussia 1872, aged 87, died, Dec 4, 1934, of chronic nephritis

George B. Peck, Woodville, R. I., Medical Institution of Yale College 1871, Civil War veteran, aged 91, died, Nov 20, 1934, of myocarditis and arteriosclerosis

Charles F. Hubbard, Chicago, Hering Medical College Chicago, 1899, member of the Illinois State Medical Society, aged 60 died, January 1, of chronic myocarditis

Harvey Brown Bashore, West Fairview, Pa., University of Pennsylvania School of Medicine Philadelphia, 1889 aged 70 died Nov 28 1934, of coronary embolism

William F. Whitten, Columbus, Ohio, Starling Medical College Columbus, 1886 aged 72 died, Nov 15, 1934 in Lake Worth, Fla. of carcinoma of the pylorus

Fay Xavier Field, Wellsboro Pa. Medico-Chirurgical College of Philadelphia 1916, served during the World War, aged 43 died, Nov 29 1934, of acute myocarditis

Donald D. McDougall, Cincinnati Hygeia Medical College Cincinnati 1895 aged 72 died Dec 11, 1934, in the Bethesda Hospital of chronic myocarditis

John Albert Copeland, Long Beach, Calif. State University of Iowa College of Medicine, Iowa City 1900 aged 59, died, Dec 5, 1934 of cerebral hemorrhage

John Harvey Adair, Wall S. D., Eclectic Medical Institute, Cincinnati, 1877 aged 82 died Nov 20, 1934, in Rapid City of carcinoma of the hard palate.

Benjamin Feltenstein, Chicago College of Physicians and Surgeons of Chicago, 1895, aged 66, died, January 2, of coronary thrombosis and myocarditis

Thomas Benton Stutzman, Denver Bennett College of Eclectic Medicine and Surgery Chicago, 1879 aged 84, died Nov 20 1934 of heart disease

Frank Elmer Cameron, Eloise Mich. Michigan College of Medicine and Surgery Detroit 1898, aged 59 died, Dec 10, 1934 of angina pectoris

Joseph Marvin Ware, Jackson Miss., Memphis (Tenn.) Hospital Medical College 1906 aged 55 died Dec 10 1934, of cerebral hemorrhage

Edward Craig Ledman, Chicago, Starling Medical College Columbus 1903 aged 60, died suddenly Dec 3 1934, of coronary thrombosis

Harry William Sullivan, Cincinnati Medical College of Ohio Cincinnati 1901 aged 56 died suddenly, Dec 3, 1934 of coronary occlusion

Horace Eaton Potter, Clifton Kan. Homeopathic Medical College of Missouri St. Louis, 1885 aged 75 died, Oct 23 1934, of senility

William Fletcher Smith, Memphis, Tenn. Baltimore University School of Medicine 1904, aged 69 died, Nov 20, 1934 of heart disease

William Elliott, Wolseley Sask. Canada University of Toronto Faculty of Medicine 1893, aged 71 died, Oct 27, 1934, of heart disease

Mosley Stuart Chandler, Columbus Miss., Atlanta (Ga.) Medical College, 1890, aged 67 died, Dec 5 1934, of amebic dysentery

John T. Wingate, Platte S. D. Albany (N. Y.) Medical College 1908, aged 53 died suddenly Nov 17 1934 of heart disease

John H. Brower, Espanola Wash. Medical College of Ohio Cincinnati, 1877 aged 84 died Nov 30 1934, of heart disease

Howard M. Fenton, Cleveland, Cleveland Medical College, 1878, aged 86 died, Dec 15, 1934 of pneumonia

Bureau of Investigation

C R EMEY GOES TO PRISON A Swindler Exposed by The Journal Is Once More in the Toils

In this department of THE JOURNAL for May 7, 1932, there was published a detailed article on a swindler whose real name seems to be Clarence Richard Emedy (sometimes spelled Emdy), but who has gone under such aliases as Don Miller, T Baker, Douglas Noble R D Whitman, etc. It was brought out in this article that Emedy had posed as an employee of the American Medical Association and had been victimizing alumni of Johns Hopkins University School of Medicine and especially members of the Sigma Chi fraternity. The article further told that Emedy's favorite story used in swindling physicians was one that had won him the name of "Spare-Tire Artist." He would represent himself as a medical student—generally from Johns Hopkins or Northwestern—and claim membership in Sigma Chi chapters at various institutions. His favorite prey were individuals whom he described as "his father's Sigma Chi classmates," and he specialized in alumni between the classes of 1895 and 1905. He had memorized the names, addresses and occupations of the class of the intended victim as well as two classes immediately before and after. His memory is incredibly good and he appears to have had little difficulty in collecting anywhere from \$5 to \$25 from at least two hundred Sigma Chis on the story that his spare tire had been stolen and that he was a little short of money. Emedy has been exposed repeatedly in *Sigma Chi Bulletin* and in the *Magazine of Sigma Chi*.

In 1927 he tried to swindle a Sigma Chi man at Wichita Falls, Texas, with the result that he was arrested, charged with forgery and sentenced to two years in prison. He got out after serving a year and a half. In December, 1930, he was arrested again in Tulsa, Okla., but unfortunately the individuals who had been swindled, because of the comparatively small sums involved were unwilling to spend any additional money in having Emedy put behind the bars.

In the spring of 1931 Emedy was working his scheme in the east. In September of the same year he was arrested by the police authorities of Montreal but while he was detained by the police of that city for a short time he got out under habeas corpus proceedings. From Montreal he went to Pittsburgh and in January 1932, was arrested for passing bad checks and sentenced to two years in the Allegheny County workhouse.

As already stated the Bureau of Investigation published its article on Emedy in THE JOURNAL, May 7, 1932 some weeks after he had been sent to the Allegheny County workhouse. The article closed with this paragraph:

For a year or so then the public will not be swindled by this impostor. As the man's record indicates that he is inherently crooked, it is probable that as soon as he is released from the workhouse in Pennsylvania he will resume his old trade.

The prophecy proved correct. Although he entered the Allegheny County workhouse on Jan. 20 1932 and had been sentenced to two years imprisonment he was released on parole at the end of ten months—in October 1932. He had not been out more than a few weeks when Mr. H. C. Burgan, Business Manager of Johns Hopkins University, reported to the Director of the Bureau of Investigation of the American Medical Association that Emedy was up to his old tricks and was swindling the families of some of the Johns Hopkins students residing in and near New York City.

Emedy then went out to the Pacific Coast and started the scheme in Los Angeles where he bilked some thirteen old grads of sums ranging from \$5 to \$25 by posing as a son-in-law of an old college classmate. He was arrested and various alumni from universities or colleges in Michigan, Massachusetts, Illinois, Pennsylvania and California living in Los

Angeles had sufficient public spirit, in spite of the small sums out of which they had been swindled, to put themselves to some expense and considerable inconvenience to appear against this swindler. As a result, Emedy was convicted and sentenced to the state penitentiary. Dr. J. Morris Simons of Los Angeles, who was written to and asked for details of the sentence, telegraphed as follows:

'Emedy transferred to Folsom Penitentiary December 27 after conviction on six counts of petty theft with prior conviction. Three sentences run concurrently three consecutively. Minimum period of imprisonment fifteen years maximum life. Parole board fixes actual sentence toward end of first year.

It is sincerely to be hoped that the parole board, when it considers Emedy's case will have before it all of the facts regarding this confirmed and inveterate swindler and will not allow any maudish sentimentality to soften either their hearts or heads. Emedy is a past master not only at the art of swindling, but in working the sympathy racket. At the time

Here are two of the free photographs taken at state expense of C. R. Emedy as he appeared in Montreal in 1931 and Pittsburgh in January, 1932.

he was sentenced to two years' imprisonment in Wichita Falls, Texas, Emedy seemed to be very penitent, studying the Bible, praying over his sins, and thereby securing the sympathy of a prominent local preacher who interceded in his behalf.

The authorities in California are to be congratulated in having proceeded promptly and intelligently.

Queries and Minor Notes

ANONYMOUS COMMUNICATIONS and queries on postal cards will not be noticed. Every letter must contain the writer's name and address but these will be omitted on request.

DERMATITIS IN STEREOTYPERS

To the Editor—Have you any information on occupational dermatitis caused by using gum paper in preparing mats for casting plates for newspaper publication? A man has a case of this and I would like the latest information.

GEORGE R. JOHNSON, M.D., Calgary, Alta.

ANSWER—At least four methods are in use in connection with stereotyping work. Causes of dermatitis may be associated with all. Calcium chloride is sometimes employed to maintain proper moisture for the mat. Nearly always mats are lubricated with oils, which sometimes are thinned with naphtha. In older methods much paste was utilized in which white and yellow dextrin flour, gum arabic and gum tragacanth were common ingredients. This paste was furnished a preservative which varied but phenol and cyanides often were used. In the past at least some mats have been treated with acid to facilitate the ready separation of the mat from the type. Lime and alum each have found some use in stereotype work. For a long time skin diseases have been attributed to flong and mat making as the source. Later, when molten metals are brought into contact with these matrices, additional sources of skin disorder arise, these, however, are not contemplated in the query. It would be difficult to establish clearly that a skin disease solely was produced by any one single factor in mat production, such as gum paper. Possibly

this may be accomplished by the making of contact tests on the skin, using paper as the test substance. In the absence of sensitization to some paper constituent and in the absence of complication due to the secondary entry of mycotic organisms, a pure chemical dermatitis may be expected to clear up in brief time with or without treatment, provided no additional exposure takes place.

AMENORRHEA

To the Editor—I would appreciate advice on treating a case of amenorrhea. A white woman aged 30 married suffered for the first time in 1924 for three months. Menstruation returned without treatment and remained regular until 1929. The second period of amenorrhea occurred in 1929 and 1930 for eleven months with an increase in body weight of about 40 pounds (18 kg.). In January 1931 a lung infiltration of the left upper lobe was found which was treated and has remained inactive since that time. At present there are no physical signs of activity reontgen examination showing a clearing up of the process and there being absence of fever and cough. Gynecologic examination reveals no abnormality. The third period of amenorrhea still in progress started one year ago. During this last year the patient has lost 40 pounds. She suffers so severely under markedly changed psychic conditions that help is really urgent. I do not think that either losing in weight or the last year's amenorrhea has any connection with the lung condition which does not show any evidence of activity and I am more in favor of the opinion of a familial constitutional condition especially if one considers that two or three sisters had too at different times amenorrhea as well as dysmenorrhea, with similar changes in body weight. To check on the lung condition I would like to do a sedimentation test. Is it possible that the sedimentation time would be influenced by such an endocrinologic condition? What could be done in regard to a hormone treatment of this case of amenorrhea? Please omit name.

M D Ohio

ANSWER—Of prime importance in the treatment of this case is assurance of the patient that the repeated periods of amenorrhea in no way indicate that her health is impaired or that they will necessarily lead to trouble. Women who have intervals of freedom from menstruation in the absence of pregnancy are just as healthy as more women who have a regular monthly flow of blood. Contrary to the general layman's opinion, the blood which women lose every month does not contain harmful substances which the body must dispose of. This blood is just as healthy as the blood in the rest of the body. Recently Aschner has revived the old idea that menstrual blood rids the body of humors or toxins, but few gynecologists agree with him. Menstruation is after all only one symptom in the series of cyclic changes that take place in women during their reproductive period. Despite the absence of the flow of blood the other changes may occur. Even gestation is possible after a period of amenorrhea because ovulation may and does occasionally take place without the occurrence of menstruation.

If this information fails to convince the patient that she is not ill because of the amenorrhea, it may be necessary to try to bring about uterine bleeding. If the patient is interested in having children it is essential to determine whether she ovulates during these periods of amenorrhea, because without ovulation there can be no pregnancy. There are a number of ways of doing this. Clinically there are two signs of ovulation, namely, intermenstrual pain, or mittelschmerz, and intermenstrual spotting, but both of these signs are rare. Recently Kurzrok, Kirkman and Creelman (*Am J Obst & Gynec* 28 319 [Sept.] 1934) added what they consider to be another indication of ovulation the sudden appearance of the follicle stimulating hormone in the urine of nonpregnant women. Knaus (*Zentralbl f Gynäk* 53 2193, 1929) maintains that in women, just as in rabbits, the uterus fails to respond to pituitary extract twenty-four hours after ovulation, and this failure to react Knaus attributes to the corpus luteum. There are other means of determining ovulation, such as the examination of the ovaries in situ, the microscopic examination of the ovaries and uterine endometrium, and the recovery of human ova from the fallopian tubes. If ovulation is present the outlook is more promising, but even without ovulation it is possible to bring about bleeding from the uterus. This may be accomplished by giving large doses of female sex hormone over a period of time and then stopping the administration abruptly. However, such endometrium is of the proliferative type only and therefore not capable of harboring a fertilized ovum. The addition of corpus luteum hormone after the administration of follicular hormone can bring about a change from the proliferative type of endometrium to the premenstrual type. However, in order to induce cyclic bleeding this treatment will have to be repeated almost indefinitely, because it is purely substitutive. Such treatment is expensive and rarely worth while.

There is no connection between the change in the patient's endocrine disturbance and the sedimentation test. The latter indicates chiefly inflammation and infection.

CHRONIC MAXILLARY SINUSITIS

To the Editor—I have two patients past 50 years of age who have chronic purulent maxillary sinusitis of many years standing. Both are greatly troubled with discharge crusting head pains neuralgia rheumatism and frequent colds. Both have had submucous resections of the septum, turbinotomies, and antrum punctures at different operations during the last fifteen years. Jackson and Coates in their recent book advise the radical operation of removing the antral mucosa entire. One of these patients consulted a well known rhinologist in Kansas City who strongly condemned the operation, saying that the Caldwell-Luc procedure usually made matters worse. He thinks that only myxomatous epithelium replaces the columnar type resulting in great crusting with bad odor and much greater discomfort. Jackson and Coates say the columnar epithelium is regenerated in dogs but how about in man? What are the facts in this matter? What treatment for these patients do you advise when they can not go to other climates? Is the radical operation ever advisable for chronic purulent maxillary sinusitis? Please omit name.

M D Missouri

ANSWER—In order to answer this question as adequately as possible, it must be assumed that the patients described have a chronic sinusitis limited solely to the antrum of Highmore. The presence of suppuration in the fronto-ethmoid group of cells with the antrum acting as a reservoir would make the whole situation much more complicated. Granting, however, that no such complication exists, it is plain that the procedures mentioned have not been sufficient to give the desired relief. It must be clearly understood that there is no one method or operative procedure that can be used after simple antrum puncture and lavage have failed to give the desired result. The operations to be considered will depend on the condition in each instance and on the experience of the operator. The character of the secretion is important. If it is thin, profuse and of foul odor, one may expect a tendency to be stubborn. Instillation of iodized poppy-seed oil with subsequent roentgenography will render valuable information as to the thickness of the sinus mucosa and the presence of polyps. It will also be necessary to make sure that there are no dental changes responsible for the chronicity.

Many surgeons feel that a large antrum window will clear up situations as described and would not care to do a more radical operation until such an antrum window had been made. There are others who feel that they can judge by the symptoms and the length of time that adequate conservative measures have already been carried out when to proceed to a more radical operation without an intervening antrum window operation.

Be that as it may, it may be stated fairly positively that the Caldwell-Luc operation cannot be categorically condemned. Properly done and for the proper indications it yields in the hands of many men a high percentage of cures or, at least, marked mitigation of symptoms.

The type of epithelium that is regenerated in man has been described by Gregor McGregor (Further Proof of the Regeneration of Mucous Membrane in the Human Antrum, *Arch Otolaryng* 14 309 [Sept.] 1931). Apart from the question of the microscopic nature of the type of epithelium encountered after operations of this character, one cannot lose sight of the fact that the epithelium now present is diseased to the point at which spontaneous cure can no longer be expected, and experience definitely shows that the new epithelium reacts in a great deal more satisfactory manner.

VASOSPASTIC DISTURBANCE OF HANDS

To the Editor—A patient complains of blueness and numbness of the hands especially when arising in the morning. This he says has been going on for about a year and is worse in damp and cold weather. During the past hot weather he had practically no symptoms but during the few days recently that have been cool his symptoms have returned. He states that this may last from thirty minutes to one hour after arising and his feet are only occasionally and slightly involved occasionally becoming numb but not changing color. The patient is a white man aged 51 of Jewish (but not Russian) faith. He is a jeweler. He stopped smoking about ten months ago. The Kahn reaction is negative. The urine is normal the blood sugar is within normal limits hemoglobin is 85 per cent (Tallqvist). Physical examination reveals nothing of pathologic importance. What diagnosis would you make? What treatment should be given? What is generally thought of the calcium and vitamin treatment as discussed by Bernheim and London (*Am Heart J* 7:588 [June] 1932) in Raynaud's disease? Would such treatment be of value here? Please omit name and address.

M D Missouri

ANSWER—This condition represents a vasospastic disturbance of the hands, apparently bilateral. The cyanosis is the result of abnormal constriction of the arterioles of the skin from cold with subsequent stasis and dilatation of the capillaries and small venules. It is an exaggeration of what occurs in normal subjects with exposure to cold. The problem involved is whether this is a primary vasomotor disturbance or one secondary to some other disease. The fact that the patient is a man aged 51,

multitates against the diagnosis of primary vasomotor disturbance, or Raynaud's disease. It is more likely that the condition represents a secondary form. One would first suspect, in a man, thrombo-angitis obliterans involving the hands. The race of the patient who is under consideration favors this diagnosis. Exact information should be obtained as to whether normal pulsations are present in the radial and ulnar arteries of both hands. If occlusion is present, the diagnosis of thrombo-angitis obliterans is tenable. In a small percentage of cases the occlusion is in the more distal arteries of the hands, and normal pulsations may be present in the wrists. Differences in the surface temperature of the individual digits, and arteriograms, will aid in deciding this. Other secondary forms of vasomotor disorder observed in the male are found with arteriosclerosis of the digital arteries, cervical rib, and neuritis. The crucial point in distinguishing between a vasomotor disorder and occlusive disease of the arteries rests on the presence or absence of pulsation in the palpable arteries of the wrists, or of the feet. Raynaud's disease in the male (incidence about 10 per cent in the male) at this age usually is not serious and usually does not lead to trophic disorders such as ulcers. Moderate protection, and exposure of the hands or the body to decreasing temperatures, carried out systematically, frequently will produce tolerance to cold, with amelioration of the cyanosis. In the secondary vasospastic disorders, treatment concerns solely the primary lesion. In thrombo-angitis obliterans the usual measures, such as contrast baths postural exercises, avoidance of local infection and trauma, and cessation of smoking are important. In arteriosclerotic disease without ulcer special treatment is not indicated. Usual precautionary measures are instituted. In the progressive forms of Raynaud's disease or thrombo-angitis obliterans involving the hands, cervicothoracic ganglionectomy is efficacious.

DI-NITROPHENOL AND NEURITIS

To the Editor—I have under my care a woman who is suffering from peroneal and anterior tibial peripheral neuritis. During the winter of 1933-1934 she had been taking di-nitrophenol for about four months. Three weeks after stopping this drug she collapsed with a high fever, sweating and profound prostration. She had a numb feeling in both legs from the knees down, and she was unable to move her toes. Her attending physicians at the time have sent a report that they attributed this to di-nitrophenol poisoning. A neurologist who saw her at that time reported the presence of peroneal and anterior tibial peripheral neuritis. She was ill for two or three weeks and then these symptoms cleared up except the numb feeling in her legs and pain in the plantar and transverse arches which still persists with no tendency to recover. At the present time she has no motor symptoms and the sensory changes are still indefinite and unconvincing but she feels that her legs both are numb. The questions I should like to ask are: Have you heard of any case of peripheral neuritis resulting from di-nitrophenol? Have you heard of any acute poisoning as long as three weeks after cessation of the drug? Can you refer me to any authority who would be in a position to consult with reference to di-nitrophenol? I would appreciate it very much if you could throw any light on this subject.

DOUGLAS ST. J. WIGLE MD Windsor, Ont

ANSWER—All the present evidence indicates that di-nitrophenol is completely excreted from the body in about three days and that the metabolism returns to the normal level in the same length of time. This is true regardless of whether the drug has been given for a few weeks or for many months, since apparently there is no accumulation of it in the body. It is therefore highly improbable that the febrile attack suffered by the patient three weeks after stoppage of the di-nitrophenol was due to this drug.

Tainter, Stockton and Cutting reported in *THE JOURNAL* (Nov. 4, 1933, p. 1472) that six of their patients developed a disturbance of taste while taking di-nitrophenol. This was probably the manifestation of a peripheral neuritis. Several mild cases of peripheral neuritis of the extremities have been observed but not yet reported in the literature. Therefore there can be no doubt that the drug can produce this symptom in a small percentage of cases. It develops slowly, with paresthesias and delayed sensory conduction, and is characteristically limited to the sensory fibers. On withdrawal of the drug improvement begins within a week or two and is complete within from one to two months. After the symptoms clear up, treatment can be resumed cautiously without further untoward effects if a lower dosage level is used. The cases of peripheral neuritis that have been observed have generally been in patients who have taken unusually large doses of the drug over prolonged periods of time.

In the present case the peripheral neuritis may have been due to the di-nitrophenol although it is difficult to explain the delayed onset except by assuming the symptoms to have been so minor as not to have attracted attention while the drug was being taken. The present "indefinite and unconvincing" nature of the symptoms might also fit in with this suggestion.

INJECTION METHOD FOR HYDROCELE

To the Editor—Will you kindly inform me of the recent method of treating hydrocele, published by Drs. N. J. Kilbourne and Charles J. Murray in the July 1932 issue of *California and Western Medicine*? I should like to know what injection fluid is used, the frequency of injections and the relative merits of this form of ambulatory treatment as compared to operative treatment of hydrocele. Please omit name.

MD Massachusetts

ANSWER—The authors of the article mentioned sought to find a solution for the injection treatment of hydrocele which would avoid pain, which would make it unnecessary for the patient to stop work while under treatment, which would not be dangerously toxic and which would be bactericidal in order to avoid infection. Their studies of various solutions led to the use of quinine hydrochloride and urethane, as suggested by Pybus of England in the same strength as used in varicose veins. The injections are made after the thorough draining of the hydrocele through a 17 gage needle. It is very important not to let the needle slip out of the sac before injection. The dosage varies from 2 to 4 cc., occasionally being 6 cc. From two to five injections are needed at intervals of one to three weeks. The use of this solution by the authors in about sixty cases has brought satisfactory long run results.

DIFFERENTIAL DIAGNOSIS OF SPLENOMEGALY

To the Editor—Kindly review the treatment and diagnosis of the following case of splenomegalia. The patient is a boy aged 16 months. The family and past history is negative except for an uneventful attack of measles at the age of 15 months. There are three brothers aged 5, 4 and 3 years all of whom have had careful physical examination and showed no evidence of splenomegalia. The patient is large and pale with a rather prominent abdomen. There are no changes of the conjunctivae. The liver seems slightly large but I am not sure of this. The spleen is quite firm and extends almost to the level of the umbilicus. Urinalysis is negative. Blood examination shows 5,360,000 red blood cells, 10,150 white blood cells, color index 0.43 and hemoglobin 46.4 per cent Sahli. There was rather marked stippling of some of the red cells. Small lymphocytes number 49 per cent, large lymphocytes 4 per cent, polymorphonuclears 46 per cent, eosinophils 1 per cent, basophils 0.

LESLIE E. MATT MD, Bridgeton N. J.

ANSWER—In a case of this description one would first want to feel certain that the tumor is due to enlargement of the spleen. It is sometimes difficult to differentiate splenic from renal tumors in infants, and an intravenous urogram may be necessary. In the second place, a little more information concerning the case would be desirable. Are the serologic tests for syphilis negative? Is the fragility of the erythrocytes normal? Should the blood count be repeated in view of the fact that the hemoglobin is low in relationship to the erythrocyte count? Have the blood smears been studied morphologically for evidence of immaturity? Is the function of the liver normal as indicated by a test for retention of dye? If the tumor is due to enlargement of the spleen and all these tests are satisfactory, the diagnosis of so-called von Jaksch's disease would be considered although almost all the cases classified as von Jaksch's disease can be said to be secondary to infection, rickets, syphilis, malnutrition or dietary deficiency. In the event that results of the foregoing tests are satisfactory and that the tumor is an enlarged spleen the treatment should consist of a balanced diet containing all the vitamins and the administration of iron, cod liver oil and calcium. It is possible that the splenomegalia may disappear as the child grows older. If this does not occur, the advisability of splenectomy should be considered at the age of 3 or 4 years.

ERYTHRODERMA DESQUAMATIVA

To the Editor—Will you kindly outline the right treatment for an infant 11 months old who is suffering from erythroderma desquamativa and has had this condition for the past five months with no relief. I am giving him Sebec ripe bananas and quartz. No relief is in sight as yet. Please do not print my name and address.

MD, California

ANSWER—The etiology of erythroderma desquamativa is still obscure. Intestinal intoxication has been considered the chief etiologic factor but avitaminosis, especially a deficiency in vitamin H, is given weight by Moro quoted by L. W. Hill (*J. Pediatr.* 4:436 [April] 1934). Moro recommends cow's milk, liver and carrot juice in the diet to supply the vitamin H deficiency. Hill feels that this symptom complex is favored in its development by a diet relatively high in fat and sugar and retarded by a diet low in fat and sugar and high in protein.

The use of vegetable soup, viosterol and autohemotherapy may be considered as further adjuncts to therapy. The use of oil applications and bland ointments locally is advised, together with the avoidance of water on the skin.

DIETL'S CRISIS AND PREGNANCY

To the Editor—Mrs R C., aged 27 married five years, has a child aged 3 years. The delivery was right occiputoposterior, and high forceps were used and episiotomy performed. One year after giving birth the patient had an appendectomy with freeing of many adhesions, which caused a malformation of the cecum. The patient still complained of old familiar pains in the lower quadrant on the right side even after the removal of the appendix. I recommended the patient to a well known gynecologist who said that the gynecologic examination was entirely negative. The patient has had many urinalyses all of which have been completely negative. The patient continued to complain of severe pain when on her feet. The sensation she had was one of a heavy weight bearing down and resting as low down as the pubic bone, and gradually radiating toward the inguinal region. There was no herniation. I then suggested cystoscopy. The cystoscopic examination showed no evidence of an inflamed bladder and no congestion of the ureters. A pyelogram showed the right kidney dropped as low as the hrim of the pelvis thereby causing a kink in the right ureter. The urologist immediately advised that a nephropexy be performed but I advised that a kidney support be tried first. I also suggested that the patient get into a knee-chest position on retiring and on arising for fifteen minutes each day. The patient took my suggestion. She has succeeded in putting on weight. Her former spastic attacks (Dietl's crisis) are less and less frequent as well as severe showing that the support has really helped her considerably. Also the patient has a normal blood pressure as well as a normal heart. Now that I have given the history of the case with I believe as many details as are necessary for a full understanding of the case I will greatly appreciate your opinion on the following questions: 1 Do you advise nephropexy even though the patient feels greatly relieved with the kidney support? 2 Even if the support does alleviate the pain and may not entirely correct the condition is there any danger of any ureteral and kidney involvement due to the descent? 3 Can this condition clear up entirely without an operative procedure? 4 Would pregnancy be advisable under such circumstances considering that the patient is solely dependent on the kidney support for comfort which I doubt she will be able to wear with a pregnant uterus distending the abdomen? 5 What other suggestion have you to help this patient along in lifting up the kidney other than that I have already advised? 6 How does the prognosis appear to you? Please omit name. M D, New York.

ANSWER—1 Although nephropexy gives satisfactory results in the majority of carefully selected cases it appears preferable to continue with the kidney support in this instance.

2 If the patient is comfortable the danger of complications is slight, perhaps no greater than one might expect after operative correction.

3 Spontaneous complete restitution will probably not occur but a clinical cure may result incident to increased body weight.

4 Pregnancy is not contraindicated although the risk of pyelitis is greater than in a normal patient.

5 Rest in various postures that mechanically favor kidney and ureteral drainage may help. The urine should be examined frequently. Surgical intervention may later be the treatment of choice if the symptoms become aggravated.

6 A prognosis without examination and study of the patient would be unwarranted, even then, prolonged observation might be required.

NICITATING SPASM

To the Editor—What is the recent modern treatment of habit spasm of the facial muscle or nicitating spasm? A man aged 24 under my care has had it for the last four years. The condition was alleviated for six months after the first year by the administration of some glandular product but I cannot find out what kind. I presume that it was some thyroid or parathyroid preparation. The patient is 5 feet 8½ inches (173 cm) in height, weighs 164 pounds (74 Kg) and is heavy set. Physical and laboratory examinations are negative in all respects. The spinal fluid shows a colloidal gold curve of 12222210000. There is no increase of globulin. No cells are present. The Kahn reaction is one plus. Rechecked two months later it was negative. All neurologic manifestations are normal. He does not complain of any pain whatever. He stops the twitching at times for ten minutes this is the longest period. When he is nervous the twitching becomes very severe. The treatment he gets at the present time consists of ultraviolet rays over his face and parathyroid extract one-half grain (0.03 Gm) daily for the four months since he came under my care but I have not noticed any improvement. The food is very much selected as in fat protein carbohydrates and vitamins with all the hygienic precautions. He received high frequency therapy over his face without any success so this was stopped. What could be the glandular extract he received after the first year which alleviated his symptoms? Shall I continue the parathyroid preparations? He has not shown any harmful effect from it nor good effects. What form of physical therapy should be applied? Please omit name and address. M D West Virginia.

ANSWER—There is no single cause for facial spasm, of which there are different varieties and consequently no single method of treatment. No description of the spasm is given, but since the term 'nicitating' is used one may perhaps assume that the spasm is of clonic form and belongs with the 'tics'. Various reflex causes of organic character occur, such as irritations of branches of the trigeminal nerve by such conditions as carious

teeth, and of the auditory nerve, errors of refraction should also be considered, especially if the spasm is bilateral. Many facial tics, however, seem to be of psychogenic origin and are due to emotional conflicts in persons constitutionally predisposed to neurotic manifestations. There is nothing in the facts given in this case to suggest that the administration of any glandular extract is indicated, parathyroid tetany is not limited to the face. The best advice that can be given is that careful search be made for sources of irritation in the region of the face and head and that should this give negative results the patient be referred to a psychiatrist for a study of his emotional life.

TREATMENT OF SYPHILIS

To the Editor—A young man contracted syphilis three years ago. Treatment with neoarsphenamine and a bismuth compound was instituted six weeks after the initial lesion and continued for eighteen months. Three negative Wassermann reactions were obtained following the treatment. The last course of neoarsphenamine according to the patient, was cut short because of severe gastro-intestinal disturbances. A recent Wassermann reaction was four plus and a small dose of neoarsphenamine, 0.3 Gm gave a severe reaction. Kindly suggest treatment. Please omit name and address. M.D. Kansas.

ANSWER—In the absence of sufficient data it is difficult to say whether this patient has received adequate treatment or not. Treatment was begun presumably in the early secondary, seropositive stage. The dosage, number of injections in a course, and intervals between treatments are not stated, nor are the dates given of the three negative Wassermann reactions. There is apparently a serologic relapse unless it can be shown that there is a fresh infection. In view of the patient's intolerance to neoarsphenamine, other methods of treatment will have to be used. It is suggested that the patient receive a short course of iodides by mouth followed by mercurial injections for six weeks and then a cautious resumption of arsenical treatment preferably bismuth arsphenamine sulphinate intramuscularly. At the end of this course a blood Wassermann and spinal fluid examination should be made and further treatment should be based on the outcome of these tests. The correspondent should be reminded that the percentage of cures in secondary syphilis is variable.

DIFFERENTIAL DIAGNOSIS OF DYSENTERY

To the Editor—A woman aged 65 has a morning diarrhea. She has from six to eight watery stools each morning without pain. In the afternoon she is better and is able to attend social functions without inconvenience. Obesity is a family characteristic. The patient has been very obese ever since earliest infancy. She is of a high strung nervous temperament and has been under great nervous strain for several years on account of financial reverses. A mixture of camphorated tincture of opium, aromatic sulphuric acid and ginger controls the diarrhea but she must keep on taking it. Rest in bed controls the diarrhea, but when she gets up it recurs. Dieting does not control the diarrhea. It has continued for nearly a year. Any suggestion as to cause and treatment will be thankfully received. Please omit name. M D., Ohio.

ANSWER—It is impossible to give a diagnosis and the treatment for the case presented without more laboratory and roentgenologic data. In cases of this type one should be sure that the stool has been carefully examined for the cyst and the motile *Endamoeba histolytica*. In addition, the blood should be studied especially for its agglutination properties for the various members of the bacillary dysentery group. It might also be of interest to know the presence or absence of free hydrochloric acid. When these facts are presented, treatment will depend, of course, on the results of these observations.

CHAULMOOGRA OIL IN ARTHRITIS

To the Editor—Please give me some information as to the rationale of the use of chaulmoogra oil in the treatment of arthritis the type of arthritis in which it is used the prognosis the dose the type of oil the frequency of treatment and the amount that may be given. Please omit name and address. M D, Texas.

ANSWER—The use of chaulmoogra oil in arthritis is entirely empirical, based on the observation made by Paul A. McIlhenny (Chaulmoogra Oil in the Treatment of Arthritis, *New Orleans M & S J* 84 182 [Sept.] 1931) at the National Leprosarium in Carville La. that secondary infectious arthritis is not encountered in leprosy patients treated with chaulmoogra oil. It has been employed in a limited number of the atrophic hypertrophic and mixed types of arthritis with allegedly good results. Gaston A. Hebert (Treatment of Arthritis with Chaulmoogra Oil, *Tri-State M J* 5 1050 [Feb.] 1933) has employed

it in chronic infectious arthritis of the atrophic type. Of the fifty-seven cases thus far reported, almost all showed some improvement during the second week of treatment, the average patient becoming symptom free in about eight weeks. To crude chaulmoogra oil is added 10 per cent of olive oil with 0.2 per cent of benzocaine, of this mixture, after an initial dose of 3 cc a dose of 5 cc is injected deep in the gluteal muscles twice a week. The treatment should be continued for some weeks after the patients have become symptom free.

FOOT AND MOUTH DISEASE—BACILLUS XEROSIS

To the Editor—About ten months ago I had a patient a white boy aged 15 years, who gradually became ill with what appeared to be an ordinary pharyngitis, lasting for three or four days without fever. About the fourth day he complained of more soreness in his throat extending out into his mouth gums and tongue. Examination at this time showed superficial ulcerations scattered over the pharynx and fauces. (The tonsils had been removed completely.) The entire mucous membrane of the cheeks gums and underneath the tongue was covered with a gelatinous gray pseudomembrane. Cultures from the mouth throat and nose were at first reported as positive for diphtheria but further study showed the organisms almost a pure culture of *Bacillus xerosis*. Since he had already been ill five or six days at the time of the positive diphtheria report he was given 40,000 units of diphtheria antitoxin after which the membrane began to separate leaving ulcerated areas where it had been. There followed a period of several days during which there was a profuse thin colorless irritating secretion from the mouth necessitating his turning his face to the side so that the secretion could run out on a towel. There had also been involvement of the eyes nose and external urethral meatus. Recovery was gradual over a period of about ten days. This boy has now presented himself with a condition resembling the onset of the illness and a similar membrane is just appearing on the inside of the cheeks. Cultures from the throat have been taken but not reported on as yet. A search of medical literature available to me fails to disclose such a clinical picture by *Bacillus xerosis*. I would appreciate any information you can give me about this condition, especially as regards treatment. Please omit name. MD Alabama.

ANSWER.—There is much in the picture given that suggests foot and mouth disease, but no mention is made of the usually associated cutaneous lesions. The association with diseased cows or goats or the use of milk, butter or cheese from sources where foot and mouth disease is present might aid in the diagnosis. Naturally the action of irritating agents taken into the mouth must be considered. The *xerosis bacillus* is one of a considerable group of bacteria found on normal and diseased mucous membranes and usually spoken of as pseudodiphtheria bacilli or diphtheroids. They are not believed to be pathogenic. The treatment should be cleansing with mild, nonirritating washes. Ulcerations may have applications of silver nitrate.

HEMATOMA AND SLOUGH AFTER INJECTION OF VARICOSE VEIN

To the Editor—A woman aged about 55 was treated for varicose veins of the legs and thighs by injections with sclerosing solutions. At the site of one injection a small hematoma appeared to form outside the vein and for several weeks dark, thick blood escaped from the needle puncture wound, although a fine needle (No 26) was used. After as much of the underlying thick blood as possible had been pressed out through this small opening the bloody discharge stopped but for about six weeks a tiny ulcer, 2 mm. in diameter has persisted at the site of the puncture. This ulcer has a depth of about 0.5 cm and its floor appears to be formed of blood clot. For about 3 cm distal to the puncture there is moderate induration with little redness or tenderness along the course of the vein which is now collapsed. This is the first time I have encountered this annoying complication of the injection treatment of varicose veins and I would appreciate any information you can give me as to the probability of spontaneous healing and suggestions as to treatment. Thus far treatment has consisted of a daily dressing and after cleansing painting with 5 per cent solution of mercurchrome and strapping with adhesive strips. The Wassermann reaction is negative. Please omit name and address.

MD California.

ANSWER.—The lesion described is a typical slough following the injection of a sclerosing solution beside the vein or into the wall of the vein. From the description given it seems probable that the sclerosing solution, the nature of which is not mentioned, has been deposited into the wall of the vein producing a necrosis of the wall and resulting in a communicating hematoma. The periphlebitis distal to the site of puncture will gradually subside, but the ulcerated area, together with its indurated margin, heals very slowly or not at all. By far the best method is to excise the entire area widely followed by primary suture. A small strip of gutta percha may be inserted for draining the wound for twenty-four hours. The excision however must not be undertaken in the presence of secondary infection.

WHY WE CAN'T DRINK SEA WATER

To the Editor—Why should a person die of thirst at sea or why is it apparently impossible to maintain the fluid needs of the human organism by sea water? Please omit name. MD Connecticut

ANSWER.—The inorganic salt content of sea water is very much higher than that of the blood of man and other terrestrial animals. The salt content of the water of the Atlantic and Pacific oceans is over 3 per cent, while that of the blood plasma of man is about 1 per cent. Most of the salt in sea water is the ordinary sodium chloride as is the case with the human blood plasma, but in the salt water is proportionately more magnesium sulphate than in the human blood plasma. It is also known that excess salts in the blood are eliminated by the kidneys. This elimination requires the elimination of an increased amount of water, which, in the first instance, is taken from the blood plasma. In the case of a person, therefore, who tries to ease his thirst by drinking sea water, the following things happen.

Because of the higher salt content of the sea water there is an increase of concentration of inorganic salts of the blood. This tends to draw water from the tissues and increase the thirst sensation. At the same time the kidneys are eliminating these excess salts together with a great deal of water from the blood plasma. This further increases thirst. Lastly, the magnesium sulphate in the sea water is not readily absorbed from the intestine, and the presence of this salt in the intestine holds back a certain amount of the water from absorption. It is therefore clear that endeavoring to stop thirst by taking sea water aggravates the thirst and hastens death. People will therefore live longer and with less discomfort by taking no water at all than by drinking sea water. People can survive longer without water if they abstain from taking food.

CELLOPHANE POISONING

To the Editor—Kindly send to me information, or refer me to literature, relative to cellophane poisoning. I have a patient working in a bakery whose work consists of wrapping rolls in cellophane, which is then sealed by heat. The fumes of the heated cellophane appear to act as a toxic agent, inducing vertigo, nausea and abdominal pain.

ISADORE SANDOCK MD South Bend Ind

ANSWER.—The constituents of cellophane are probably not always the same, as it is believed that variation may be introduced to meet special requirements. Somewhat speculatively it is noted that moisture-proof cellophane may be coated with a lacquer, wax or possibly tricresyl phosphate. Primarily cellophane is cellulose. It is not known that the complete combustion of this material in small quantities would give rise to harmful amounts of any such agents as nitrous gases, acid vapors or carbon monoxide. In fact, it is well known that cellophane to the amount of many tons is burned daily, sometimes in open incinerators, without the development of any body of information that the heating or burning of this material introduces any practical dangers. Thousands of workers daily seal up cellophane wrappers, either by heat or by other fixatives, without the development of injurious effects attributable to the chemical properties of cellophane. Therefore it is doubted that the condition described in this query may be attributed to cellophane as a toxic agent. In many bakeries irrespective of the presence of cellophane workers suffer from nausea, vertigo, headaches and pallor. In part, such disturbances are due to excessive temperatures in some bakeries high humidity, odors, carbon monoxide dusts, undue fatigue and physical responses to endless monotony. It is believed that this type of injury source should be considered in connection with the present situation rather than the direct attribution of the disorder to cellophane.

SHORTENING OF STUMP AFTER AMPUTATION

To the Editor—A patient had his leg amputated about five years ago. Measurement taken a few days after operation is supposed to have shown that the stump measured $6\frac{1}{2}$ inches below the knee. Examination at this time shows that the stump including the pad measures about $4\frac{1}{2}$ inches. The stump of the tibia measures approximately $4\frac{1}{2}$ inches. I should like to know first whether it is possible for this much atrophy to take place in a period of five years. Secondly how much if any shortening of the bone of a stump will take place in that length of time? Please omit name.

MD Michigan

ANSWER.—It is not probable that the difference in the measured length of the stump as stated can be explained on the basis of atrophy. Little if any shortening of the bone of the stump has been noticed even after the lapse of years. Measurements of stump length are not accurate unless made by the same surgeon each time and using the same landmarks.

ICEBOX OR ELECTRICAL REFRIGERATION

To the Editor—There has been a great deal of discussion about the use of ice in domestic refrigeration as contrasted with electrical methods according to whether one talks to a member of an ice company or to a General Electric Company salesman. I have always used the old fashioned icebox with perfect satisfaction but am even chided by some of my colleagues. Beyond the mechanical conveniences of the electrical machine are there many valid hygienic advantages?

FRANK R. SMITH JR., Baltimore

ANSWER—Economy is claimed to be an advantage by both sides in the controversy. Advocates of ice claim that there is less drying out of foods than with electrical refrigeration.

When the refrigerant gas is poisonous, a health hazard may result from leaks in the mechanical refrigerator, as shown by the experience with methyl chloride in Chicago several years ago.

CHLOASMA

To the Editor—Do you have any suggestions regarding the removal of darkly pigmented blotches about the neck and upper part of the chest of a healthy mother aged 34? These occurred at the time of her second pregnancy two years ago and were called chloasma at the time. Other pigmentary changes include premature and complete graying—almost whitening—of the scalp hair and of one eyebrow and corresponding eye lashes. Please omit name.

M D Iowa

ANSWER—Clinical investigation and further advance in knowledge of the glands of internal secretion indicate that lesions such as those mentioned are usually ascribed to endocrine disturbances. No treatment is necessary. In fact, no satisfactory specific therapeutic hormone substance is as yet available.

Surgical removal of the pigmented blotches is not indicated unless for cosmetic reasons. In the event that removal of the pigmented areas is contemplated, the surgeon should avoid squeezing the lesions with tissue forceps at the time of excision (avoidance of traumatism is more important than wide excision in the prophylaxis against cancer).

TOXICITY OF LUPINES

To the Editor—A patient of mine an Italian aged 48 recently presented himself to me complaining of abdominal swelling and a feeling of tightness in the stomach with slight nausea and a history of having vomited once. On examination extreme distention of the intestines was the only positive finding. There had been no bowel movement for thirty hours. The condition was one of intestinal obstruction without obvious cause combined with a negative history for gastro intestinal trouble. On close questioning about his recent diet it developed that the day before he had eaten some lupines a beanlike legume which is a popular food with Italians and is eaten after the hard kernel has been left standing in water for a week or more. This patient had not consumed any of this food in many years. On questioning other Italians I found that they all remarked on the poisonous properties of this legume on certain occasions. The patient finally passed much flatus after several high enemas had been given but not until a surgical consultation had been held. The distention did not return and he recovered quickly. I would greatly appreciate information on the pharmacology and toxicology of lupines and should like to know if in your opinion this paralytic ileus could have been due to a toxic effect of this legume or the water in which it was soaked.

GRANT GUILLEMET M D Niagara Falls N Y

ANSWER—It is well known that many lupines have toxic qualities. Alkaloids (lupinine, lupinidine, lupanine) have been isolated from them. These in general have a conium-like action, i. e., they produce paralysis of the nerve endings of voluntary muscles. As they also have an action on the vegetative nervous system, there is a possibility that the results observed might have been due to insufficient soaking of this lupine or to the consumption of some of the water in which it was soaked.

ADDICTION TO COCAINE

To the Editor—In your opinion could the use twice daily over a period of years of an oily solution containing 1 grain of cocaine to the ounce applied within the nose result in cocaine addiction? Please omit name.

M D Pennsylvania

ANSWER—It could and most probably would result in a habit. Cocaine administered daily to any 100 persons for a year would make many addicts, because few, less than 15 per cent, would be satisfied with the result obtained without increasing the amount used per dose or increasing the number of doses used daily. The cocaine habit is almost always a pleasure or vicious habit, without true withdrawal abstinence symptoms as found in morphinism. The patient can be deprived of cocaine immediately with no treatment and without any serious symptoms of collapse developing. However, cocaine, like diacetylmorphine, will produce a psychosis or change in

the moral character more quickly than will morphine. If the cocaine in the solution is discontinued for a few weeks it will be possible to check how much or how little of a habit exists. Before the enactment of the Harrison Narcotic Law many cocaine addicts were made by the use of the so-called catarrhal cures (containing cocaine) advertised extensively to the public.

TREMORS AFTER THYROID ADMINISTRATION IN HYPOTHYROIDISM

To the Editor—A patient with severe hypothyroidism was entirely relieved of his symptoms by a daily dose of 4 grains (0.26 Gm.) of thyroid U S P but a definite tremor developed that was especially annoying when writing. The tremor disappeared when the medication was discontinued. While I was determining the maintenance dose which seems to be about 2 grains (0.13 Gm.) daily, the tremor returned being apparent even with 1 grain (0.065 Gm.) daily. What therapeutic maneuver would you recommend that might permit adequate medication and still avoid the tremor? Please omit name.

M D

ANSWER—A strong suspicion of the original diagnosis of hypothyroidism arises when small doses of thyroid produce toxic symptoms, such as tremor, a low metabolic rate occurs in some individuals because of fatigue, malnutrition or some other nonthyroid depressing mechanism. These patients while having a subnormal metabolic rate do not exhibit either external or internal signs of myxedema. In particular, the blood cholesterol is not elevated. Furthermore, they are not benefited by thyroid and fatigue and nervousness are often increased. It may be that the patient falls into this group. If, however, there is incontrovertible evidence that thyroid deficiency exists and thyroid is required, the tremor might be controlled by the use of tincture of stramonium on the assumption that some underlying neurologic cause of the tremor has been activated by the thyroid medication.

BURNS OF THE LARYNX

To the Editor—Can you furnish me with any literature on external burns of the larynx especially electrical burns? I have a patient who came in contact with a high tension wire which struck him at the larynx destroying the skin and tissues down to the laryngeal cartilages. These cartilages are now sloughing. I am wondering whether there is anything in the literature of a similar occurrence.

HOWARD L. MITCHELL M D Lexington, Va.

ANSWER—The literature on this subject is almost wholly lacking, and the only reference we have been able to find is the following:

Foerster A. Changes in Tracheal Mucosa in Victim of Fire. *Deutsche Zeitschr f d ges gerichtl Med* 19 293 1932

FRACTURE OF PATELLA AFTER MUSCLE ACTION

To the Editor—Kindly advise me concerning the rarity or frequency of fracture of the patella due to muscular action as landing on one foot forcibly with semiflexed knee, or sudden muscular action the knee semiflexed to extricate the foot when tightly held by foreign control. Kindly omit name.

M D Ohio

ANSWER—Fracture of the patella itself is not a frequent occurrence as a result of sudden muscular action.

Rupture of the extensor apparatus is more common, especially above the patella.

MYCOTIC ABSCESS

To the Editor—Several weeks ago (THE JOURNAL, Nov 10 1934, p 1472) in replying to a query concerning the cause of a mycotic abscess following a dental operation you stated that the fungi must have been in the anesthetic solution and thus injected into the tissue. Of course this is one possibility but I do not believe that the stock anesthetic solution is in much use today by dentists. The majority of them use ampules or boil up their solutions when needed.

I wish to call attention to a very probable cause for the mycotic abscess. It must be remembered that yeast cells and other types of fungi, especially of the nocardial group are common mouth inhabitants. I have demonstrated actinomycetes like fungi deep in the tissues in cases of chronic and recurrent gingivitis. I have also been able to recover yeast cells from tissues covered by dentures especially in cases of so-called rubber sore mouths. Incidentally I have also recovered this micro-organism from inflamed areas covered by gold dentures. Whether these fungi are pathogenic or not has to be determined but it is a fact that they are found in diseased areas much more frequently than in normal ones.

It is my belief that these mycotic abscesses are due to inoculation by the hypodermic needle carrying fungi present in or on the mucous membrane deeper into the tissues during the course of an injection.

Professor of Histology and Embryology University of Virginia Sixth
edition Cloth Price \$7.50 Pp 738 with 610 illustrations New York
& London D. Appleton Century Company Inc. 1934

The seemingly lucrative field of histology textbook writing
has made it possible to review a number of textbooks that have
been put on the market either as new books or as new editions
of older textbooks Such a comparison is of interest because it
shows what teachers of histology consider to be essential for
medical students With the rapid accumulation of practicable
knowledge in all fields within the last few years, it has become
an increasingly difficult problem to know what portions of a
subject to stress for beginning students and what portions to
leave out Although it is impossible for the average medical
student to grasp all of the subjects in his crowded curriculum
in any great detail, it certainly seems necessary that students
not only should be well trained from the point of view of a
"trade school"—that is to say, with respect to histology, that
they should be able to recognize tissues and organs for their
later work in pathology—but also should learn something about
the present growing points of the science, something of present-
day problems and methods of investigation Students beginning

a course early in their medical curriculum should also acquire something of the scientific attitude and be trained in critical evaluation of facts. In other words, a course such as histology is of value to the medical student not only for its own sake but for the purpose of training the student to think, since it comes early in the curriculum.

Cowdry has written a textbook from a new point of view. He has omitted many structures ordinarily studied in a course in histology and has stressed particularly those of which considerable physiologic information exists. He has considered the blood vascular system as the great integrator of the body and has presented the various organic systems in relation to the body as a whole and particularly their relation to the blood vascular system. If the student is able to grasp the correlation between structure and function by means of a textbook of this kind he will have acquired much more valuable information than by merely crowding his memory with mental images of histologic preparations. Cowdry justly makes the criticism that most textbooks of histology repeatedly illustrate the obvious, and he has not attempted to illustrate structures which (according to his theory) the student can study for himself in the usual collection of microscopic material handed out in courses of histology. He has taken his references for the most part from the classic literature or from quite recent articles and on the whole has tried to be impartial in his conclusions. In many places, however, he has accepted as facts statements made in the recent literature without explaining thoroughly enough the methods by which such conclusions were reached and in a few instances has swallowed work of dubious value whole. A book of this kind, courageously written, could not help but be one-sided in many subjects, but it is well to let beginning students know that there are still problems to be solved in histology, a conception they will never get from most other textbooks. Most of the illustrations are excellent, and many of the data of the various systems of the body are summarized in tables. There is too much cytologic detail to be of use to medical students. The references have been well chosen, they are references from which students who wish to do more than the minimum required amount of work in the course would get the most benefit. It remains to be seen whether freshmen medical students will be able to comprehend the text, and to learn histology from slides without some sort of atlas or picture guide. But Cowdry is on the right track, surely medical students can grasp important generalizations without cramming, parrot-like, all the insignificant details of a subject only one of many, after all, in their curriculum.

Schafer has many more illustrations, mainly from photographs, than in previous editions, most of them good, but otherwise the plan of the book remains much the same as in former editions. This textbook is primarily an objective atlas with less text than any of the other textbooks of histology and has always been a valuable laboratory manual for the students to use while they are looking at slides. It is exactly the sort of "picture book" which Cowdry has criticized. Medical schools devoting a minimum amount of time to the course in histology will probably find this book of greatest value in teaching students the essentials of the subject, as the title states. The text has always been quite conservative but it is didactic in the usual British medical school compendium manner, and necessarily many of the statements are inaccurate and unjustified in the light of the most recent work in histology. This textbook contains more neuro-anatomy than the other textbooks of histology. In the United States most medical schools have a separate course in neuro-anatomy and the chapters on the nervous system in this textbook do not fill the requirements of a textbook on neuro-anatomy. This textbook then can be recommended not as the best textbook of histology but as the best short textbook for students with a minimum of time.

Jordan has gone to considerable pains to bring his best seller of previous years down to date. But many of the illustrations are quite unsatisfactory (there are too many diagrams) and the text is not concisely enough written from the standpoint of a medical student with a crowded curriculum. Just for example, the illustration labeled "active human mammary gland" on page 469 is more typical of a mammary gland of pregnancy than of a lactating gland. There are many inaccuracies in the text, mainly due to quotations from the older literature. It is

well for the students to have reference to classic papers that represent an actual advance in our knowledge of a scientific subject, but there is no point in giving space to old papers of doubtful value. If we must have quotations from the literature, let us have the most recent literature on the subject. There is insufficient reference in this textbook to the physiologic aspects of organs, although more than is to be found in Schafer.

One of the greatest difficulties that a freshman medical student has is correlating the information he acquires in his anatomic courses and his physiologic courses. From this point of view the best textbook of the series being reviewed is the one by Cowdry.

Medical students who are to meet only human tissues henceforth should acquire a familiarity with the microscopic appearance of human material primarily. There are so many differences in the histology of human material and material from the common laboratory animals that unless the student has enough time allotted to his course in histology to allow him to learn considerable comparative histology it is far wiser to restrict his time to the study of human material. To be sure much of our most valued information has been obtained from experimental animals, but there is no point in having a medical student learn the microscopic appearance of a uterus that does not menstruate or of a pig's liver with its large amount of interlobular connective tissue, or of a dog's thymus, whose life cycle differs so widely from that of the human being. This statement presupposes that the human material must be adequately preserved to show the normal structure. Many of the illustrations in Schafer and Jordan, therefore, are unsatisfactory—but Cowdry's fewer illustrations meet this objection.

The moral of this comparative review is that probably any textbook is good enough. Medical sciences are so interlocking that the medical student will probably compensate for the deficiencies in any one course by the information he acquires in his other courses.

Die Kinder männlicher und weiblicher Morphinisten (Frage der Kelm und Fruchtschädigung Erbgang der Psychopathie) von Prof. Dr. Kurt Pohlisch. Boards. Price 5.80 marks. Pp. 82. Leipzig: Georg Thieme 1931.

The author reviews experimental proof of alterations of hereditary factors in animals and plants due to environment; for instance mutations characterized by changes in the eye, wings and body color in the fruit fly (*Drosophila*) following exposure to x-rays. Changes in lower life following exposure to solutions of chemicals have been less pronounced. Proof of mutations in man due to certain environmental agencies, such as alcohol is questioned. He considers morphine addiction a fertile field for this type of genetic analysis. The sexual functions are usually inhibited and the toxic period of the subject's life is sharply separated from the normal.

A total of 1929 adult addicts, 1348 male and 581 female, were genetically analyzed. The children produced before or after (115) and during the period of addiction (280) were examined for mental and physical defects. Those born during the period of addiction of one or both parents were 69.6 per cent normal, 25.8 per cent psychopathic (without psychosis), 2.9 per cent feeble-minded, 1.2 per cent epileptic and 1.4 per cent physically defective. Those born before or following the period of addiction of the parents were 68.9 per cent normal, 26.2 per cent psychotic, 3.9 per cent feeble-minded, 1.0 per cent epileptic and 1.8 per cent physically defective. The comparative study showed no significant difference in the two groups. Furthermore the parents and other close blood relatives showed a similar high percentage of defects. The descendants of four addicts were traced to the second and third generations with similar results. The observations indicated that the defects are inherent and transmissible and not due to the use of morphine.

Considerable space is devoted to an analysis of the course of pregnancy and confinement of sixty-two addicted mothers. An increase in fetal movements occurred when the usual dose of morphine was decreased or delayed. Premature births were frequent. Abstinence symptoms similar to the syndrome observed in adults appeared shortly after birth and increased in severity up to the third day unless morphine was administered or the mother's milk became established. The infant

mortality was high (143 per cent), usually occurring on the second or third day, owing to abstinence. There was considerable delay in development during the first month of life, but thereafter the infants progressed favorably. Certain infants were also found to develop abstinence symptoms when deprived of the mother's milk, showing that they received a sufficient amount of morphine from this source to maintain addiction.

The mental characteristics of the usual confirmed addict are described and certain general differences noted from those peculiar to the alcohol addict. The question of sterilization is discussed. The apparent decrease in the prevalence of addiction the fact that the average age level is higher than formerly, and the comparative sterility of the morphine addict are cited as factors against the sterilization of this group in Germany.

Benign Encapsulated Tumors in the Lateral Ventricles of the Brain: Diagnosis and Treatment. By Walter E. Dandy, M.D., Adjunct Professor of Surgery, Johns Hopkins University. Cloth. Price \$4.50. Pp. 189 with 63 illustrations. Baltimore: Williams & Wilkins Company, 1934.

This monograph deals with a pathologically heterogeneous group of encapsulated tumors, which were situated in the lateral ventricles of the brain. That the author, among the thousands of brain tumors recorded in the medical literature, was able to find only twenty-five similar tumors indicates that the book deals with a great rarity. One might ask why a monograph should be written on such a rare condition, which has no constant clinical or pathologic characteristics. The answer is given in the introduction—to point again to the value of ventriculography, now generally recognized. The book abounds in dogmatic statements. That this precision in diagnosis [by ventriculography] is not only easy and certain but is attainable without risk to life or function is not strictly true. The author has been able to find in the literature only one other such tumor disclosed and removed at operation; he overlooked, among others, the case of Cushing (Studies in Intracranial Physiology and Surgery, Oxford Medical Publications, 1925, pp. 42-43), which was calcified and visible in the roentgenogram though the author states that the one of Barré and Metzger is "the only one in the literature." Many will be surprised to find that any one ever thought or taught that "every tumor below the surface of the brain is a glioma" (in quotation marks in the book but reference not given).

There are now no tumors giving signs or symptoms that cannot be accurately diagnosed, precisely localized and disclosed at operation. Perhaps, but not necessarily removed for the author goes on to say: "The other invasive tumors give signs and symptoms that are all too frequently indistinguishable from those of the encapsulated type." The statement "It is far better to apply the term 'ependymal glioma' to a tumor that by practical test is sharply differentiated from all other gliomata in the brain" is simply absurd. The statement on page 30 that tumors of the choroid plexus "metastasize through the blood to all parts of the body" is unjustified by the evidence given. There is no proof that the tumor of Atlee arose from the choroid plexus. It is useless to multiply further such citations. After a consideration of small primary tumors not giving symptoms and of malignant tumors, the author begins a detailed and profusely illustrated account of his fifteen cases. The case reports are sometimes carelessly written. For example, in case 1, page 9, it is stated that "there is no iron pigment, whereas the subtitle to figure 2A says 'The small black masses are iron pigment.' In case III the subtitles of figures 4A and 4B seem to be reversed. The tumor in case VII is obviously of leptomeningeal origin. Case X is not a ventricular tumor, as the author admits. The tumor in case XI is also obviously a leptomeningioma. There follows a detailed analysis of the signs and symptoms the upshot of which is that there are no characteristic signs and symptoms. The next chapter points out that these tumors must be localized by ventriculography and states that the use of ventriculography has made it possible to overcome all the diagnostic defects in this group of tumors." Not quite all the author does not tell how many times he has been misled into performing useless explorations for malignant invasive tumors. The chapter on treatment illustrates again the well known technical virtuosity of the author. The author's cases are a welcome addition to the casuistics of brain tumors.

Considérations sur l'étiologie des maladies infectieuses. Par le Docteur Rappin, professeur honoraire de l'École de médecine. En collaboration avec M. le Docteur Doueslain, médecin à Clisson (Loire Inf.). Paper. Pp. 130 with illustrations. Nantes: Imprimerie de Bretagne, 1934.

In the preface the author acknowledges that his opinions are contrary to predominating doctrines. However, he believes that even as Pasteur abandoned ancient conceptions the time will come through an evolution of ideas relating to pathology and heredity when many modern views will be abandoned and old concepts be reborn. The book philosophizes on general pathology and the etiology and pathogenesis of infectious diseases. The contents are based on observations and studies made during the life of the author. He refers to the discovery of filtrable viruses and the era before Pasteur, discusses much of Pasteur's work, and mentions the latter's impetuosity in defending his opinions. There are portrayed some of the advances made in bacteriology and this is accompanied by a discussion of the origin of disease and of epidemics. Influenza, cerebrospinal meningitis and diphtheria are among the infectious diseases considered from an epidemiologic point of view. Considerable attention is given to the spontaneous origin of infectious disease and outside influences. Cancer is referred to as an infectious disease the origin of which is within the body and is cited as an example of this theory. There are frequent quotations from many investigators, past and present. The author states that all real human science tends toward the realization of two great problems, the nature of matter and the nature of life. He places much credence in the views of the ancients concerning the influence that climatic and meteorological conditions have on disease. He says we are entering on a new era in the study of disease and must consider it in relation to exterior and cosmic elements. The book sets forth a sequence of events in the progress of bacteriology. It is attractive from a historical standpoint. It presents an interesting philosophy relating to the future study of disease by one well qualified to express his views.

Recent Advances in Allergy (Asthma, Hay Fever, Eczema, Migraine, etc.). By George W. Bray, M.B., Ch.M., M.R.C.P., Physician in Charge of Children's Department, Prince of Wales Hospital, London. With foreword by Arthur F. Hurst, M.A., M.D., F.R.C.P., Senior Physician, Guy's Hospital. Second edition. Cloth. Price \$5. Pp. 608 with 106 illustrations. Philadelphia: P. Blakiston, Son & Company, Inc., 1934.

The fact that a second edition has been called for within three years after the first one is proof of the excellence of the book. The author has the unique ability to say what he wants in a brief and lucid manner. His language is simple and readily understandable. His sayings are especially effective, for example, he says "It is interesting to note that the best results have always been obtained by the original observer and poorer results by subsequent investigators." His tables are good and after he quotes the literature, which he does extensively, he summarizes the observations briefly and then gives his own opinion in intelligent fashion. The book covers the subjects of asthma, hay fever, eczema, migraine and the other allergic diseases and has a fair dissertation on these sicknesses. The discussion of the relationship of the nose and nasal sinuses to allergy is an extremely fair one and reconciles many of the arguments between the allergists and the nose and throat specialists. Although Bray's experience has been chiefly with children and his own opinions are necessarily derived from observations on children, he includes so much work on adults that the book is helpful to all those interested in allergy. On a few minor points one must disagree with the author. He favors group skin tests, a system that makes the finding of positive reactions more difficult. He includes enuresis as an allergic phenomenon, this is quite doubtful. He sterilizes his syringes and needles by running them through a sterile saline solution. He condemns the use of ultraviolet radiation in bronchial asthma (many investigators think this procedure quite valuable). In his next edition, which one hopes will be forthcoming in a few years, the author should devote much more space to the section on the elimination of the specific causes of bronchial asthma. This portion of the book is very weak and much too brief and implies a lack of success. No mention, for example, is made of the fact that it is necessary to eliminate thoroughly foods to which the child is hypersensitive. In general, however, the book is an excellent one for allergists, for general practitioners and for advanced medical students.

a course early in their medical curriculum should also acquire something of the scientific attitude and be trained in critical evaluation of facts. In other words, a course such as histology is of value to the medical student not only for its own sake but for the purpose of training the student to think, since it comes early in the curriculum.

Cowdry has written a textbook from a new point of view. He has omitted many structures ordinarily studied in a course in histology and has stressed particularly those of which considerable physiologic information exists. He has considered the blood vascular system as the great integrator of the body and has presented the various organic systems in relation to the body as a whole, and particularly their relation to the blood vascular system. If the student is able to grasp the correlation between structure and function by means of a textbook of this kind he will have acquired much more valuable information than by merely crowding his memory with mental images of histologic preparations. Cowdry justly makes the criticism that most textbooks of histology repeatedly illustrate the obvious, and he has not attempted to illustrate structures which (according to his theory) the student can study for himself in the usual collection of microscopic material handed out in courses of histology. He has taken his references for the most part from the classic literature or from quite recent articles and on the whole has tried to be impartial in his conclusions. In many places, however, he has accepted as facts statements made in the recent literature without explaining thoroughly enough the methods by which such conclusions were reached and in a few instances has swallowed work of dubious value whole. A book of this kind, courageously written, could not help but be one-sided in many subjects, but it is well to let beginning students know that there are still problems to be solved in histology, a conception they will never get from most other textbooks. Most of the illustrations are excellent, and many of the data of the various systems of the body are summarized in tables. There is too much cytologic detail to be of use to medical students. The references have been well chosen; they are references from which students who wish to do more than the minimum required amount of work in the course would get the most benefit. It remains to be seen whether freshmen medical students will be able to comprehend the text, and to learn histology from slides without some sort of atlas or picture guide. But Cowdry is on the right-track; surely medical students can grasp important generalizations without cramming, parrot-like, all the insignificant details of a subject, only one of many, after all, in their curriculum.

Schafer has many more illustrations, mainly from photographs, than in previous editions; most of them good, but otherwise the plan of the book remains much the same as in former editions. This textbook is primarily an objective atlas with less text than any of the other textbooks of histology and has always been a valuable laboratory manual for the students to use while they are looking at slides. It is exactly the sort of "picture book" which Cowdry has criticized. Medical schools devoting a minimum amount of time to the course in histology will probably find this book of greatest value in teaching students the essentials of the subject, as the title states. The text has always been quite conservative but it is didactic in the usual British medical school compend manner, and necessarily many of the statements are inaccurate and unjustified in the light of the most recent work in histology. This textbook contains more neuro-anatomy than the other textbooks of histology. In the United States most medical schools have a separate course in neuro-anatomy and the chapters on the nervous system in this textbook do not fill the requirements of a textbook on neuro-anatomy. This textbook then can be recommended not as the best textbook of histology but as the best short textbook for students with a minimum of time.

Jordan has gone to considerable pains to bring his best seller of previous years down to date. But many of the illustrations are quite unsatisfactory (there are too many diagrams) and the text is not concisely enough written from the standpoint of a medical student with a crowded curriculum. Just for example, the illustration labeled 'active human mammary gland' on page 469 is more typical of a mammary gland of pregnancy than of a lactating gland. If we must have quotations from the literature, let us have the most recent literature on the subject. There is insufficient reference in this textbook to the physiologic aspects of organs, although more than is to be found in Schafer.

One of the greatest difficulties that a freshman medical student has is correlating the information he acquires in his anatomic courses and his physiologic courses. From this point of view the best textbook of the series being reviewed is the one by Cowdry.

Medical students who are to meet only human tissues henceforth should acquire a familiarity with the microscopic appearance of human material primarily. There are so many differences in the histology of human material and material from the common laboratory animals that unless the student has enough time allotted to his course in histology to allow him to learn considerable comparative histology it is far wiser to restrict his time to the study of human material. To be sure much of our most valued information has been obtained from experimental animals but there is no point in having a medical student learn the microscopic appearance of a uterus that does not menstruate or of a pig's liver with its large amount of interlobular connective tissue, or of a dog's thymus whose life cycle differs so widely from that of the human being. This statement presupposes that the human material must be adequately preserved to show the normal structure. Many of the illustrations in Schafer and Jordan, therefore, are unsatisfactory—but Cowdry's fewer illustrations meet this objection.

The moral of this comparative review is that probably any textbook is good enough. Medical sciences are so interlocking that the medical student will probably compensate for the deficiencies in any one course by the information he acquires in his other courses.

Die Kinder männlicher und weiblicher Morphinkisten (Frage der Keim und Fruchtschädigung, Erbgang der Psychopathie) von Prof. Dr. Kurt Pöhlisch. Boards. Price 5.80 marks. Pp. 82. Leipzig: Georg Thieme, 1934.

The author reviews experimental proof of alterations of hereditary factors in animals and plants due to environment; for instance mutations characterized by changes in the eye, wings and body color in the fruit fly (*Drosophila*) following exposure to x-rays. Changes in lower life following exposure to solutions of chemicals have been less pronounced. Proof of mutations in man due to certain environmental agencies, such as alcohol, is questioned. He considers morphine addiction a fertile field for this type of genetic analysis. The sexual functions are usually inhibited and the toxic period of the subject's life is sharply separated from the normal.

A total of 1,929 adult addicts, 1,348 male and 581 female, were genetically analyzed. The children produced before or after (115) and during the period of addiction (280) were examined for mental and physical defects. Those born during the period of addiction of one or both parents were 69.6 per cent normal, 25.8 per cent psychopathic (without psychosis), 2.9 per cent feeble-minded, 1.2 per cent epileptic and 1.4 per cent physically defective. Those born before or following the period of addiction of the parents were 68.9 per cent normal, 26.2 per cent psychotic, 3.9 per cent feeble-minded, 1.0 per cent epileptic and 1.8 per cent physically defective. The comparative study showed no significant difference in the two groups. Furthermore the parents and other close blood relatives showed a similar high percentage of defects. The descendants of four addicts were traced to the second and third generations with similar results. The observations indicated that the defects are inherent and transmissible and not due to the use of morphine.

Considerable space is devoted to an analysis of the course of pregnancy and confinement of sixty-two addicted mothers. An increase in fetal movements occurred when the usual dose of morphine was decreased or delayed. Premature births were frequent. Abstinence symptoms, similar to the syndrome observed in adults, appeared shortly after birth and increased in severity up to the third day unless morphine was administered or the mother's milk became established. The infant

mortality was high (14.3 per cent), usually occurring on the second or third day, owing to abstinence. There was considerable delay in development during the first month of life, but thereafter the infants progressed favorably. Certain infants were also found to develop abstinence symptoms when deprived of the mother's milk, showing that they received a sufficient amount of morphine from this source to maintain addiction.

The mental characteristics of the usual confirmed addict are described and certain general differences noted from those peculiar to the alcohol addict. The question of sterilization is discussed. The apparent decrease in the prevalence of addiction, the fact that the average age level is higher than formerly, and the comparative sterility of the morphine addict are cited as factors against the sterilization of this group in Germany.

Benign Encapsulated Tumors in the Lateral Ventricles of the Brain. Diagnosis and Treatment. By Walter E. Dandy, M.D., Adjunct Professor of Surgery, Johns Hopkins University. Cloth. Price \$4.50. Pp. 189 with 83 illustrations. Baltimore: Williams & Wilkins Company, 1934.

This monograph deals with a pathologically heterogeneous group of encapsulated tumors, which were situated in the lateral ventricles of the brain. That the author, among the thousands of brain tumors recorded in the medical literature, was able to find only twenty-five similar tumors indicates that the book deals with a great rarity. One might ask why a monograph should be written on such a rare condition, which has no constant clinical or pathologic characteristics. The answer is given in the introduction—to point again to the value of ventriculography, now generally recognized. The book abounds in dogmatic statements. That "this precision in diagnosis [by ventriculography] is not only easy and certain but is attainable without risk to life or function" is not strictly true. The author has been able to find in the literature only one other such tumor disclosed and removed at operation, he overlooked, among others, the case of Cushing (*Studies in Intracranial Physiology and Surgery*, Oxford Medical Publications, 1925, pp. 42-43), which was calcified and visible in the roentgenogram though the author states that the one of Barré and Metzger is "the only one in the literature." Many will be surprised to find that any one ever thought or taught that "every tumor below the surface of the brain is a glioma" (in quotation marks in the book but reference not given). "There are now no tumors giving signs or symptoms that cannot be accurately diagnosed, precisely localized and disclosed at operation." Perhaps, but not necessarily removed, for the author goes on to say "The other invasive tumors give signs and symptoms that are all too frequently indistinguishable from those of the encapsulated type." The statement "It is far better to apply the term 'ependymal glioma' to a tumor that by practical test is sharply differentiated from all other gliomata in the brain" is simply absurd. The statement on page 30 that tumors of the choroid plexus "metastasize through the blood to all parts of the body" is unjustified by the evidence given. There is no proof that the tumor of Atlee arose from the choroid plexus. It is useless to multiply further such citations. After a consideration of small primary tumors not giving symptoms and of malignant tumors, the author begins a detailed and profusely illustrated account of his fifteen cases. The case reports are sometimes carelessly written. For example, in case 1, page 9, it is stated that there is no iron pigment, whereas the subtitle to figure 2A says "The small black masses are iron pigment." In case III the subtitles of figures 4A and 4B seem to be reversed. The tumor in case VII is obviously of leptomeningeal origin. Case V is not a ventricular tumor, as the author admits. The tumor in case XI is also obviously a leptomeningioma. There follows a detailed analysis of the signs and symptoms the upshot of which is that there are no characteristic signs and symptoms. The next chapter points out that these tumors must be localized by ventriculography and states that the use of ventriculography has made it possible to overcome all the diagnostic defects in this group of tumors. Not quite all the author does not tell how many times he has been misled into performing useless explorations for malignant invasive tumors. The chapter on treatment illustrates again the well known technical virtuosity of the author. The author's cases are a welcome addition to the casuistics of brain tumors.

Considérations sur l'étiologie des maladies infectieuses. Par le Docteur Rappin, professeur honoraire de l'École de médecine. En collaboration avec M. le Docteur Doussaln, médecin à Clisson (Loire Inf.). Papier. Pp. 136 with illustrations. Nantes: Imprimerie de Bretagne, 1934.

In the preface the author acknowledges that his opinions are contrary to predominating doctrines. However, he believes that even as Pasteur abandoned ancient conceptions the time will come through an evolution of ideas relating to pathology and heredity when many modern views will be abandoned and old concepts be reborn. The book philosophizes on general pathology and the etiology and pathogenesis of infectious diseases. The contents are based on observations and studies made during the life of the author. He refers to the discovery of filtrable viruses and the era before Pasteur, discusses much of Pasteur's work, and mentions the latter's impetuosity in defending his opinions. There are portrayed some of the advances made in bacteriology, and this is accompanied by a discussion of the origin of disease and of epidemics. Influenza, cerebrospinal meningitis and diphtheria are among the infectious diseases considered from an epidemiologic point of view. Considerable attention is given to the spontaneous origin of infectious disease and outside influences. Cancer is referred to as an infectious disease the origin of which is within the body and is cited as an example of this theory. There are frequent quotations from many investigators, past and present. The author states that all real human science tends toward the realization of two great problems, the nature of matter and the nature of life. He places much credence in the views of the ancients concerning the influence that climatic and meteorological conditions have on disease. He says we are entering on a new era in the study of disease and must consider it in relation to exterior and cosmic elements. The book sets forth a sequence of events in the progress of bacteriology. It is attractive from a historical standpoint. It presents an interesting philosophy relating to the future study of disease by one well qualified to express his views.

Recent Advances in Allergy (Asthma Hay Fever Eczema Migraine etc.). By George W. Bray, M.B., Ch.B., M.R.C.P., Physician in Charge of Children's Department, Prince of Wales Hospital, London. With foreword by Arthur F. Hurst, M.A., M.D., F.R.C.P., Senior Physician, Guy's Hospital. Second edition. Cloth. Price \$5. Pp. 603 with 106 illustrations. Philadelphia: P. Blakiston's Son & Company, Inc., 1934.

The fact that a second edition has been called for within three years after the first one is proof of the excellence of the book. The author has the unique ability to say what he wants in a brief and lucid manner. His language is simple and readily understandable. His sayings are especially effective, for example, he says "It is interesting to note that the best results have always been obtained by the original observer and poorer results by subsequent investigators." His tables are good, and after he quotes the literature, which he does extensively, he summarizes the observations briefly and then gives his own opinion in intelligent fashion. The book covers the subjects of asthma, hay fever, eczema, migraine and the other allergic diseases and has a fair dissertation on these sicknesses. The discussion of the relationship of the nose and nasal sinuses to allergy is an extremely fair one and reconciles many of the arguments between the allergists and the nose and throat specialists. Although Bray's experience has been chiefly with children, and his own opinions are necessarily derived from observations on children, he includes so much work on adults that the book is helpful to all those interested in allergy. On a few minor points one must disagree with the author. He favors group skin tests, a system that makes the finding of positive reactions more difficult. He includes enuresis as an allergic phenomenon, this is quite doubtful. He sterilizes his syringes and needles by running them through a sterile saline solution. He condemns the use of ultraviolet radiation in bronchial asthma (many investigators think this procedure quite valuable). In his next edition, which one hopes will be forthcoming in a few years, the author should devote much more space to the section on the elimination of the specific causes of bronchial asthma. This portion of the book is very weak and much too brief and implies a lack of success. No mention, for example, is made of the fact that it is necessary to eliminate thoroughly foods to which the child is hypersensitive. In general, however, the book is an excellent one for allergists, for general practitioners and for advanced medical students.

Praktische Psychiatrie Von Primarius Dr. med. et phil. Friedrich Schulthor. Paper. Price 10.50 marks. Pp. 486. Berlin & Vienna: Urban & Schwarzenberg, 1934.

This book is written for the general practitioner, it has some shortcomings and many virtues, the latter being definitely more numerous. The book is addressed to Austro-German physicians, the bulk of whose patients are still treated in their homes even under circumstances that in America are considered to render hospitalization imperative. Part of the book is consequently devoted to detailed instructions on how to administer hydrotherapy and other therapeutic measures in the home. Even this, however, is of benefit to any one not experienced in institutional work. There is also a tendency to deal dogmatically with problems of pathogenesis and etiology. Aside from these rather negligible faults, the book may safely be recommended to any one who desires to orient himself in the field of psychiatry and demands a manual that is neither too technical nor too simple. The chapters on psychopathic personality, epilepsy and alcoholism are especially well done, a feature that renders the book more valuable to the practitioner.

Essentials of Injection Treatment of Internal Hemorrhoids. By Thomas F. McNamara, M.D., Staff of St. Mary's Hospital, Rochester, N. Y. Foreword by Benedict J. Duffy, M.D., Chief of Staff of St. Mary's Hospital, Fabrikoid. Price \$3.50. Pp. 117 with 6 illustrations. Rochester, N. Y.: Medical Press, 1934.

This work covers largely the author's technique in the treatment of 1,100 cases of internal hemorrhoids. Injection methods were used exclusively. In view of the well known tendency to recurrence after such treatment, his case might be more convincing if his work included a record of a follow up to show how large a proportion of his cases recurred. The same is true of his practice of "snipping off" hypertrophied papillae. If this alone prevents their recurrence, his experience will be exceptional. There are interesting clinical anecdotes illustrating the author's tact and sagacity in handling patients and the detailed directions may prove helpful to practitioners who wish to use this method exclusively.

Grundzüge der pathologischen Physiologie. Von Dr. med. Hans Lucke, Privatdozent für Innere Medizin in Göttingen. Paper. Price 0.00 marks. Pp. 195. Berlin: Julius Springer, 1934.

As the author states in the preface, the purpose of his book is not to offer a review of normal and pathologic physiology or clinical symptomatology, but to summarize for the students in a practical way the underlying processes responsible for the corresponding clinical and laboratory observations. An attempt to elucidate complicated scientific problems has been intentionally dropped. As the book is to serve merely as an introduction to the study of pathologic physiology and is not competing with more exhaustive works, bibliographic references are omitted. The text is subdivided into chapters on special organic metabolism, vitamins, hormones, total metabolism, mineral and water metabolism, formation of sediments and stones, blood, pigments, respiration, circulation, urinary organs, digestion, the nervous system, thermoregulation, infections, immunity and allergy. One finds a few omissions which for completeness should be included, for instance, bacteriophage and the patch test for allergy. The book is thoroughly modern, covering every recent advance of real value, and contains a wealth of material presented in a simple, concise manner. A perusal of the book will prove of great value not only for students but also for graduates who wish to refresh and replenish their knowledge of this important subject.

Good Food at Low Cost. By R. T. Devereux, M.D., Pediatrician, Chester County Hospital. Introduction by S. C. Schmucker, Ph.D., Chester County Emergency Child Health Committee. Under the Auspices of the Chester County Medical Society. Paper. Pp. 38. Westchester, Pa.: The Society, 1934.

This book, intended for the housewife, is a result of the nutrition program of the Chester County Emergency Child Health Committee formed under the auspices of the Chester County Medical Society and as a unit of the Emergency Child Health Committee of Pennsylvania. It states in simple and practical form some of the latest information on foods for promoting the proper feeding of people, especially children. Recipes and menus with an explanation of the essential foods and the methods for their purchase and preparation are included.

The less money to spend for food, the more important it is to spend it wisely. The booklet serves the purpose of instructing on this problem and should enable the average citizen to prepare well balanced diets at low cost. It will be especially helpful to those interested in the emergency feeding of the poor.

Medizinische Kolloidlehre. Herausgegeben von Prof. Dr. L. Lichtwitz, Dr. Dr. Haph. Ed. Liesegang und Prof. Dr. Karl Spiro. Lieferung 17. Paper. Price 5 marks. Pp. 840. 028 with 1 illustration. Dresden & Leipzig: Theodor Steinkopff, 1934.

This instalment deals, first, with the relation between pharmacology and colloid chemistry. Starkenstein reminds us that all biologic manifestations must ultimately be referred to colloid chemical alterations. Disease, poisoning and cure are all results of such changes. Colloid chemistry has decided the age old controversy between humoral and cellular pathology in favor of both, for the entire living body is a colloidal solution. As examples of the revolutionary change in view that colloid chemistry has forced on pharmacology, the author discusses briefly the newer understanding of diastatic ferment action, of the adsorption and distribution of remedies, of diuretics and diaphoretics, of inhibition of inflammation, and of drug influences on purine metabolism. No less profound and enlightening is Liesegang's chapter on "Strahlentherapie," which attempts, by giving numerous references to recent literature, to open up the treasury of the latest views to those who have not been able to keep abreast of some of the most recent advances in the biology of irradiation. Hans Moser's chapter on dressings is as full of practical suggestions as are the others of theoretical interest. The work is maintaining in this instalment the high standards set by previous ones.

Chirurgie du pancréas. Par P. Brocq, professeur agrégé à la Faculté de médecine de Paris, et G. Migoniac, professeur à la Faculté de médecine de Toulouse. Paper. Price 75 francs. Pp. 427 with 75 illustrations. Paris: Masson & Cie, 1934.

Instead of "Surgery of the Pancreas," a more appropriate title for this monograph would be "Surgical Diseases of the Pancreas," as of 427 pages only one and one half (in the chapter on injuries of the gland) are devoted to the description of the surgical approach. There are chapters on traumas of the pancreas, acute pancreatitis, chronic pancreatitis, cysts, syphilis, tuberculosis, stone formation, fistulas, malignant tumors and anatomic anomalies of the gland. In each chapter a short historical review is followed by a discussion of the etiology, pathologic anatomy, pathogenesis, clinical manifestations and treatment of the described lesion. Case reports and statistical data are abundant, illustrations scanty, numerous writers are mentioned by name, but bibliographic references are lacking, certainly an inexcusable omission in a monographic type of work. The recent trend to a more conservative treatment postponing the operation till the "shock stage" is passed, did not receive any consideration. While these shortcomings detract considerably from the value of the work, this is nevertheless a significant contribution to the French medical literature.

Hamlet: An Analytic and Psychological Study. By Fayette C. Ewing, M.D. Paper. Price 50 cents. Pp. 32. Boston: Stratford Company, 1934.

Ernest Jones, writing in the *American Journal of Psychology* (21:72 [Jan.] 1910) on the "Oedipus complex as an explanation of Hamlet's mystery, a study in motive," speaks of "those Shakespearean critics who have enjoyed no special opportunities for penetrating into the obscurer sides of mental activities and who base their views of human motive on the surface valuation given by the agents themselves—to whom all conduct, whether good or evil at all events springs from conscious sources." To this category seemingly belongs the author of this short essay, which is written almost entirely in the literary style and is hardly analytic or psychologic according to the lights of modern psychopathology. Dr. Ewing, who is apparently quite well versed in Hamlet lore, having for many years collected all he could find that has been published by physicians concerning the mental stability of Hamlet, contents himself with a simple objective study to show that Hamlet was sane. The old quarrel as to whether or not Hamlet feigned a psychosis is revived by citing passages from the play, and the conclusion is offered that the prince of Denmark acted as any reasonable individual would under similar trying circumstances. Nothing new is added.

to clarify the great riddle of Shakespeare's most distinguished character for this particular ground has been gone over time and again by scores of psychiatrists. A work such as that of Jones, which penetrates deeply into the more important matters of the motivations and mechanisms of the mind and the unconscious behavior of Hamlet, lends considerably more to the unraveling of the main problem, which essentially consists in the cause of Hamlet's hesitancy in seeking to obtain revenge for the murder of his father. Dr. Ewing's venture is more a labor of love than a scientific psychological study.

Medicolegal

Medical Practice Acts Licensed Practitioner Convicted of Practicing Medicine Without a License—F. B. Needham and A. H. Bray were convicted of "practicing medicine without a license," in that they unlawfully treated a woman for a supposed cancer of the breast. They appealed to the criminal court of appeals, Oklahoma.

Needham was not a licensed physician in Oklahoma, although he had for a number of years operated the Needham Cancer Sanitarium, in Oklahoma City. Bray apparently had a license authorizing him to practice medicine in Oklahoma. The evidence on behalf of the state showed that Needham and Bray told the patient that a secret formula of Needham's, a paste, when applied to the human flesh would destroy cancerous growths, if present, but that if there was no cancer the paste would not burn the flesh. By this method, they said, it could be determined if cancer was present. At their solicitation, the woman finally submitted to the test. Shortly thereafter she felt a burning sensation in her breast and returned to the sanitarium. Needham and Bray told her that the test was positive proof that she had cancer and, for an additional fee, they gave her additional treatments. Needham applied the paste and Bray covered it with tape. Subsequently when the pain in her breast became unbearable, the woman was taken to a hospital, where physicians removed the paste and tape revealing "a shocking physical condition." The state chemist testified that he had made a chemical analysis of paste similar to that used on the woman and that it had a heavy test for zinc, a heavy test for chlorides and "the gummy substance had a high content of zinc chloride." Zinc chlorides, he testified, have a caustic and erosive reaction and cause burns and blisters on the human flesh whether cancerous or otherwise.

The theory of the defense was that instead of Bray assisting Needham Bray was the actual practitioner and that Needham only assisted him in emergencies. Testifying in their own behalf they both admitted the only treatment used in the sanitarium was Needham's so-called secret formula and that Needham applied the paste and Bray did the taping in the treatment administered to this particular woman. Four treatments, in all, were given to the woman; they testified Bray being present for the first two treatments and Needham applying the last two in Bray's absence. The fees received for the treatment of all patients, they testified, were divided, one third going to Bray and two thirds to Needham. Bray was employed by Needham to take charge of the sanitarium and conduct the treatments they claimed, and that while Needham sometimes assisted Bray, he never acted alone except in emergencies.

Many errors were complained of by the appellants, said the criminal court of appeals, but since their own evidence clearly showed them to be guilty of the offense charged, the judgment of the trial court must be affirmed unless the errors complained of are of such a fundamental nature as to require a reversal. Among other things, the appellants contended that the trial court erred in refusing to permit the introduction of evidence showing that Needham had consulted attorneys including the county attorney, and had been advised by them that if he employed a regular licensed physician to conduct his sanitarium he would not be violating the law. Counsel for the appellants admitted that they could find no authorities to support this contention. This was not surprising, observed the court, since there probably are no such cases. The trial court properly rejected this evidence. An accused cannot prove as a defense

that he acted on the advice of counsel in committing the act complained of, because if such were the law it would be placing the advice of counsel above the law itself. Each person charged with an offense must know what the law is, and he acts at his own peril. After examining the entire record, the criminal court of appeals concluded it to be apparent that the errors complained of were not such as to result in any material injury to the appellants and the judgment of conviction was affirmed.—*Needham and Bray v. State (Okla.)*, 32 P. (2d) 92.

Malpractice Judgment in Suit for Fee as Bar to Subsequent Action for Malpractice—The defendant-physician obtained in a justice's court a judgment against the plaintiffs for the reasonable value of the services rendered by him in treating their child. In contesting the payment of this fee, the plaintiffs contended that the services rendered were valueless, in that the physician did not exercise the degree of care, skill and intelligence required of physicians and surgeons in the locality. Subsequently, the plaintiffs instituted the present suit against the defendant-physician to recover damages for alleged malpractice in treating the child. The trial court gave judgment for the defendant, holding that since the question of negligent treatment had been adjudicated in the suit instituted in the justice's court and had been determined in favor of the physician, the judgment of the justice's court constituted a bar to the instant suit for damages based on alleged negligence. The plaintiffs appealed to the district court of appeal, second district, division 2, California.

The plaintiffs contended that since a justice's court was not a court of record, it was impossible to tell what matters were actually litigated and that the judgment rendered in the justice's court did not show on its face that the question of negligent or careless treatment was litigated. But, said the district court of appeal, a reporter's transcript and the pleadings and instructions to the jury did show that this question was presented to the court and jury, and even though it had not been specifically set up as a defense, the question was necessarily involved. "A physician or surgeon taking charge of a case," continued the court, "impliedly represents that he possesses, and the law places upon him the duty of possessing, that reasonable degree of learning and skill that is ordinarily possessed by physicians and surgeons in the locality where he practices." *Hesler v. California Hospital Co.*, 178 Cal. 764, 766, 174 P. 654, 655. If he does not possess such learning and skill, or if, possessing it, he fails to use it, he is guilty of malpractice, and in every action to recover for services rendered by a physician or surgeon in which either the lack of skill and learning are necessarily involved it needs no argument to demonstrate that a physician or surgeon who does not show at the trial that he possesses such skill by proving that he is licensed to practice his profession, and at least by presumption that he used the same in performing the services rendered, would not be entitled to recover. In other words, in our opinion, such questions are actually and necessarily included in an adjudication of his right to recover even in a default case, and particularly so where, as here, an answer is filed which expressly raised an issue thereon which was presented for decision as here shown. The district court of appeal, therefore, agreed with the trial court that the adjudication on the question of negligent or careless treatment by the justice's court was conclusive on that question, and barred the plaintiffs from prosecuting the present action.—*Olney v. Cavell (Cal.)*, 32 P. (2d) 181.

Pharmacy Practice Acts Conclusiveness of Finding That Applicant Is of Good Moral Character—In November 1927 Watkins was granted a pharmacist's license in Louisiana after examination. He subsequently moved to Mississippi and in 1931 was there licensed as an assistant pharmacist. In 1932 a law was enacted in Mississippi (Laws, 1932,

I. Bray, although a licensed practitioner was convicted of practicing medicine without a license apparently by virtue of section 1808 Oklahoma Statutes 1931. All persons concerned in the commission of crime whether it be felony or misdemeanor, and whether they directly commit the act constituting the offense or aid and abet its commission though not present are principals. Since Bray assisted Needham unlawfully to practice medicine he himself also became liable as a principal under the Oklahoma statute quoted.

c 277) making it mandatory that the state board of pharmacy license as a registered pharmacist any person of good moral character who had, after examination, been licensed to practice pharmacy in another state prior to Dec 31, 1927. Watkins applied to the Mississippi state board of pharmacy for a pharmacist's license, but the board took no action on his application. He then brought mandamus to compel the board to issue the license. The trial court ordered the board to act on the application but it declined to command the board to issue the license, seemingly holding that the board should pass on Watkins' good moral character. Watkins appealed to the Supreme Court of Mississippi, division B.

Since the Mississippi pharmacy practice act, said the Supreme Court, requires that all applicants for assistant pharmacist licenses prove their good moral character, the issuance of such a license to Watkins in 1931 was a recorded adjudication by the board that he was of good moral character, which is conclusive on the issue. The board urged, however, that when Watkins applied for a license to practice as an assistant pharmacist, only a superficial examination was made into his moral character and that the board now intends to make a thorough investigation. But, answered the court, the board cannot be heard to say that it failed in its duty fully to investigate into Watkins' good moral character prior to issuing him an assistant pharmacist's license. Public judicial and quasi-judicial records must rest on a more secure foundation than would be the case if any such contention as the board now makes were allowed to prevail. Nor may the force of the former adjudication as to Watkins' good moral character be avoided by a suggestion that there may have been a change in that regard. The legislature has authorized a review of judgment on that issue only in proceedings to revoke a license and the only causes, stated in the statute, justifying revocation of a license is the conviction of the holder of unlawfully selling habit-forming drugs or intoxicating liquor. The court pointed out, moreover, that there was no intimation in the record that Watkins was not at present of good moral character.

The court accordingly reversed the judgment of the lower court and directed the state board of pharmacy to issue Watkins a license to practice as a registered pharmacist.—*Watkins v. Mississippi State Board of Pharmacy (Miss)*, 154 So 277.

Workmen's Compensation Act Lymphatic Leukemia Allegedly Aggravated by Trauma—At the time of his death in January 1931, Kizer was 59 years old. Until December 1930 his general health had been good, although for several years previously he had varicose veins in both legs. Sometime in December 1930 red spots, varying in size from a dime to a quarter, appeared on both of his feet, some of his toes were swollen and at times the varicose veins pained him but he did not consult a physician. On Jan 12, 1931, in the course of his employment, he bruised the calf of his left leg. The following day he had to cease work and go home. He never worked thereafter. January 16 he went to a clinic for examination, where it was ascertained that he had a white cell count of 119,000 per cubic millimeter and "hemorrhagic bleeding" under the skin of the calf of the left leg at or near the point where it had been bruised. On January 19, "hemorrhagic bleeding" appeared under the skin of the calf of the right leg. The following day the bruise or red blotch on the calf of the left leg was improved and was "fading out" but the blotch and "hemorrhagic bleeding" on the right leg were worse. On January 27, Kizer was found in a stupor, with partial paralysis. He was taken to a hospital where he died that day. His blood count on his entrance to the hospital was over 400,000 per cubic millimeter. After autopsy, death was attributed to acute lymphatic leukemia. Claiming that death was due to complications arising from the bruise on his left leg, received in the course of his employment, his widow sought compensation under the Nebraska compensation act. From a judgment of the district court, Lancaster County, affirming the refusal of the compensation commission to award compensation, the widow appealed to the Supreme Court of Nebraska.

For the claimant to recover compensation said the Supreme Court, she must show with reasonable certainty that the workman's death was caused by injuries resulting from an accident

arising out of and in the course of his employment. This, the court concluded, the widow failed to do. The testimony of medical experts called by the employer and his insurance carrier amply sustained the conclusion reached by the commission and by the lower court that there was no proof adduced of any relationship between the industrial injury complained of, the bruise, and the acute lymphatic leukemia of which the workman died. These experts testified that medical authorities are unanimous in the opinion that trauma can neither cause acute lymphatic leukemia nor aggravate it. These experts denied that the bruise on the calf of the workman's left leg, received on January 12, in any manner caused or contributed to his death on January 27. Only one medical expert, called by the widow, testified that the trauma was a contributing cause of the death. The Supreme Court accordingly affirmed the judgment of the lower court denying compensation to the widow.—*Beatrice Creamery Co v Kizer (Neb)*, 254 N W 690.

Pharmacy Practice Acts Sale of Aspirin and Citrate of Magnesia—Four prosecutions were instituted under the pharmacy practice act of California. The defendants were found guilty in each case and they appealed to the appellate department, superior court, Los Angeles County, where their appeals were consolidated.

In two of the cases the defendants were charged with operating pharmacies, stores or shops where drugs were sold at retail, without having registered pharmacists in charge thereof. By section 1 of the pharmacy practice act, said the court, a store or shop where drugs are sold at retail is not a pharmacy, for the purposes of the act, unless a sign containing the words "pharmacist," "pharmaceutical chemist," "apothecary," "druggist," "pharmacy," "drug store" or "drugs" is on the store or in it. The complaints failed to allege, and there was no proof adduced to show, that one of these signs was on or in the store owned by the defendants. The court accordingly reversed the convictions in these two cases.

In the two other cases the defendants were charged with selling drugs and medicines, to wit, aspirin and citrate of magnesia, without being registered under the pharmacy practice act. The defendants contended that the complaints in their cases were defective because they did not negative the exceptions contained in the pharmacy practice act. The court held that exceptions need not be negated in a complaint. Further, the court held, it was not reversible error for the trial court to permit a certain witness to testify that aspirin and citrate of magnesia are drugs or medicines, despite the fact that the witness was not qualified so to testify. Courts take judicial notice that these two substances are drugs or medicines, said the court. The defendants also contended that the sale of aspirin and citrate of magnesia was excepted from the operation of the pharmacy practice act by section 12, which provides that the act shall not apply to "registered, trade marked or copyrighted proprietary medicine, registered in the United States Patent Office." To bring an article within this exception, said the court, two things are necessary: (1) the article must be a proprietary medicine, and (2) it must be registered, trade marked, or copyrighted. registered in the United States Patent Office. We are not required to determine whether or not the two articles are proprietary medicines, continued the court, because, even if it be assumed that they are, the record contained no evidence that the articles had been registered, trade-marked, or copyrighted in the United States Patent Office. But because of an error in assessing penalties on these defendants, the cases were remanded to the trial court with directions to impose the proper penalties.—*People v Garcia (Calif)*, 32 P (2d) 445.

Malpractice Award of Compensation as Bar to Suit for Malpractice—A workman says the Supreme Court of Oklahoma, may recover from the employer under the Oklahoma workmen's compensation act not only for an industrial injury but also for any aggravation thereof due to the malpractice of the physician selected by the employer. Under such circumstances, an award of compensation under the compensation act will bar a suit for damages for malpractice that the workman subsequently institutes against the physician.—*Markley v White (Okla)*, 32 P (2d) 716.

CENTRAL SOCIETY FOR CLINICAL RESEARCH

Seventh Annual Meeting, held in Chicago Nov 2 and 3 1934

(Concluded from page 150)

The Diagnostic Features of Acute Pancreatitis

DR. EDWIN G BANNICK, Rochester, Minn Acute pancreatitis is usually incorrectly diagnosed. The usual textbook description, since it applies to the rare fulminating hemorrhagic case, is misleading in most instances. The more common and milder cases usually are mistaken for severe cholecystic disease. These observations are confirmed by a careful study of the records of forty-seven patients whose symptoms were proved by surgery or necropsy to have been due to acute pancreatitis. Certain facts brought out in this study should result in more accuracy in the diagnosis, treatment and prognosis.

DISCUSSION

DR. S. A. SHELburne, Dallas, Texas I wonder if Dr Bannick had the opportunity to do the dextrose tolerance test in the acute cases. I had the privilege of observing over a long period of time a man with recurrent attacks of pancreatitis the symptoms of which fit in with those mentioned here. A few hours after the worst symptoms had subsided, I did a dextrose tolerance test. This man showed the most profound changes. The blood sugar was elevated to 350 or 400 mg per hundred cubic centimeters and the urine always showed sugar. I saw him in three distinct attacks at intervals of four months and repeated the studies in each attack. Within ten days or two weeks after the attack the dextrose tolerance test was entirely normal.

DR. E. L. TUOHY, Duluth, Minn In the larger group that was proved by operation, what was the degree of fat necrosis found at operation?

DR. JOHNSON MCGUIRE, Cincinnati Was cyanosis of unusually marked degree noted in these cases? In the few cases that I have seen in which the diagnosis of acute pancreatitis was confirmed by operation or autopsy, cyanosis was extreme and out of proportion to the cyanosis that one observes in any other acute abdominal condition.

DR. EDWIN G BANNICK, Rochester, Minn As to the dextrose tolerance, I do not think there is any doubt that the results reported by Dr Shelburne would be the case. In the cases that I reported the diagnosis was unsuspected and these records show only the ordinary urinalysis, and in only a few was the blood sugar determination made. I am convinced that if blood sugar determinations were made in every suspected case of acute pancreatitis there would be a higher incidence of carbohydrate disturbance than was noted in my series of cases and, of course, a dextrose tolerance test would probably show a still higher incidence. In regard to the question concerning the conditions found at operation all of these cases were either surgical or postmortem cases. I included no case that did not show some degree of fat necrosis. In selecting these forty-seven cases I passed over a good many in which a definite pancreatitis was present but cholecystic disease, such as empyema of the gallbladder, was so severe that it would have been difficult to evaluate the symptoms and changes that were due to the pancreatitis, and this was my chief idea in collecting this group of cases. The question of cyanosis in acute pancreatitis has been raised. I don't know just what it is due to but there is no doubt that it occurs in some cases particularly the hyperacute group. I have noted it in a few cases and it has been a peculiar sort of cyanosis and particularly noticeable in the face

and abdomen. I rather doubt the diagnostic value of this observation, but it probably adds a little something to the picture when taken as a whole.

Gastroscopy Present Status and Value in Diagnosis of Gastric Disease

DR. RUDOLF SCHINDLER, Chicago The invention of the flexible gastroscope has overcome the chief difficulties of gastroscopy. The examination can be conducted on the ambulatory patient. It can be done with greater ease and less discomfort to the patient, the danger of perforation is practically eliminated, and it permits a wider field of vision than was possible with the rigid instrument. Gastroscopy is of great importance in determining the frequency of chronic gastritis, the correlation of its appearance with the clinical picture, and to evaluate therapeutic procedure. It has a wide application in observing gastric ulcer. Duodenal and pyloric ulcers are not favorably situated for this direct examination. Benign tumors of the stomach are easily seen, and in all probability beginning carcinomas can be located better by the gastroscope than with other methods now employed.

DISCUSSION

DR. WALTER L PALMER, Chicago I am sure that the method will give much more information about gastric disease. In the beginning I had some misgivings about it. Dr Schindler has succeeded in examining every patient I have sent to him. Many patients quite willingly acquiesced to subsequent examinations for the purpose of studying the progress of the lesion.

DR. LEON SCHIFF, Cincinnati I should like to ask Dr Schindler whether he has ever observed a true jejunal ulcer through the gastroscope. This type of lesion is frequently difficult to demonstrate on roentgen examination. I should also like to know whether or not he has seen gastric ulcer in various phases of healing. Just what changes occur and how much time is required for complete healing to take place?

DR. J. A. EVANS, La Crosse, Wis Has the author been able to apply therapeutic measures through the gastroscope?

DR. RUDOLF SCHINDLER, Chicago I have observed jejunal ulcers several times, but they are not found as frequently in stomachs that have been operated on as is a very severe gastritis. I have observed the healing ulcer very often. By examining these patients weekly with the gastroscope I have observed that generally in six and one-half to seven weeks the ulcer heals completely. It is not possible to give therapeutics through the flexible gastroscope, because it is filled with lenses.

The Formation and Fate of Derivatives of Bilirubin

DR. C. J. WATSON, Minneapolis Information in this study was gained in several different experiments. 1 Feeding of a known amount of crystalline bilirubin by means of a duodenal tube to a patient with complete common duct obstruction (neoplasm). Results (a) There was no evidence for bilirubin absorption from the bowel. (b) The majority of the urobilinogen formed was reabsorbed and not accounted for in the feces or urine, with an accurate quantitative method. 2 Comparison of urobilinogen excretion in the urine with that in the feces in cases of advanced liver disease. In several of these, the amount in the urine was from two to four times that in the feces, thus bearing out the evidence obtained in the first experiment as to urobilinogen reabsorption. 3 Study of feces obtained from an ileostomy. Evidence for the formation of mesobilirubin in the transition of bilirubin to urobilinogen. 4 Study of the relationship of oxidation products of urobilinogen, evidence indicating that mesobilirubin on further oxidation gives coproporphyrin. Appearance of mesobilirubin absorption after melting of a crystalline iron chloride molecular compound of urobilin. This indicates a close chemical relationship between urobilin and mesobilirubin.

DISCUSSION

DR. M. A. BLANKENHORN, Cleveland I hope that some of the difficulties of making quantitative studies in biliary pigment is appreciated. Dr Watson has made progress. I wonder whether he has taken into consideration, when he has given 10 mg of bilirubin to a patient with common duct obstruction, the bacterial flora necessary to transform bilirubin into the preparation that is recognized as urobilinogen. In my hands,

attempting with the aid of a chemist *intra vitro* transformation of these chemicals, we found that a very careful bacterial arrangement has to be set up in which the type of organism is important. With the aid of Dr Eecke, our bacteriologist, we found it was almost impossible to set up bacterial flora from pure strains. I should like to ask how long the patient has had his intestinal acholia. If he has had it a long time I would expect him to be no longer capable of transforming urobilinogen. I think that the finding of large amounts of altered pigment is emphasized by the conditions found in human gallbladder bile. Human gallbladder bile removed at autopsy will almost always contain large amounts of a substance that can be identified as urobilinogen or urobilin. In some instances it exceeds, gram for gram, the amount of bilirubin. I have been concerned in the last few years with the ratio of urobilin and bilirubin collected from the gallbladder. This ratio is quite variable. It suggests variables in absorption as well as variables in the ability of the liver to excrete the substance.

DR C J WATSON, Minneapolis. In answer to Dr Blankenhorn's question, the jaundice in both of these instances was of fairly long duration, in one about two months and the other three months, and presumably quite complete for most of that period. In both, the jaundice was due to neoplastic obstruction of the common duct. It is realized that these patients are not normal and that the bacterial flora may be altered. The stools in these instances were carefully examined for their bilirubin derivatives and it was possible to obtain crystalline stercobilin after the administration of bilirubin. It was not possible prior to the period of the experiment to isolate any derivative of bilirubin. Following the feeding of bilirubin the amount in the serum did not increase, to indicate that there had been any resorption of bilirubin itself. This experiment should be repeated a number of times before one can say that no bilirubin is resorbed. I think that the existing evidence, to which Dr Blankenhorn's work certainly contributes a great deal, is in favor of the fact that there is no resorption of any appreciable amount of bilirubin from the bowel.

The Vascular Response to Venesection, with Observations on So-Called Bloodless Venesection

DRS WILLIAM A BRAMS and J S GOLDEN, Chicago. Patients with congestive failure were used in the experiments. Venous pressure was determined by a modified Moritz-Tabora apparatus. Readings were taken every five minutes for one hour after venesection. The blood pressure and pulse rate were determined at similar intervals. Bloodless venesection was accomplished by constricting three extremities to obstruct venous return, but not arterial. The same observations were made as with blood letting. Bloodless venesection showed little effect on venous pressure, blood pressure or pulse rate. Blood letting up to 800 cc showed little effect on blood pressure or pulse rate. Venous pressure fell rapidly, to return in part after from twenty to thirty minutes. The best results were seen in previous high venous pressure.

DISCUSSION

DR. SAMUEL B GRANT, St Louis. About ten years ago I did some arterial punctures in patients with congestive heart failure to study the oxygen saturation of arterial blood. I found after venesection that they consistently showed an increase in the oxygen saturation of the arterial blood, which is another factor not absolutely proved.

DR. W S MIDDLETON, Madison, Wis. There are three points that should be emphasized. First, the advisability of the indirect method in patients whose vascular status must be borne in mind, in other words, one has not made repeated punctures but has tried to maintain a blood way through the apparatus in the case of the Moritz-Tabora closed method. The ability to duplicate results by the indirect method in repeated observations should be brought out. The second point relates to the application of venesection, as the authors state, it should be utilized in the case showing venous hypertension and not arterial hypertension. This is the pathologic physiologic situation to be treated. Third, I think the speed of withdrawal is an important factor. One should try to do one's blood letting within five minutes. If it takes fifteen minutes to release the load on the right side of the heart, I think too much time has been expended to effect maximum benefit. The work of Eyster

and Meek at Madison showed that the blood volume must be reduced to a given degree to decrease the size of the heart. Practically, if one is after this physiologic end one will draw enough blood, or at least 500 cc. for a person weighing 150 pounds (68 Kg).

DR J S GOLDEN, Chicago. The puncture need not be repeated if the needle is allowed to remain in the vein and one assures oneself that no blood is allowed to stay in the needle. There were no multiple punctures in these cases. We found that, when a quantity of blood was removed in a very short period, the venous pressure did drop very rapidly. Immediately after completion of the venesection there was a rise to a secondary level, from which the total level was approached. When we took a longer time the drop was more gradual, but there was no rapid return to the secondary level.

Blood Cyanates in the Treatment of Hypertension

DR M HERBERT BARKER, Chicago. The blood level of cyanates and the urinary clearance has been studied in relation to the dosage of potassium and sodium thiocyanate in patients with hypertension. A great variation in clearance and in the blood cyanate level is noted in each case on a given dosage. In general, blood pressure reductions have been observed in all the cases studied. A significant decrease in blood pressure level together with symptomatic relief has been quite regularly noted in the cases in which the dosage was gaged by the blood cyanate level. The optimum level for the blood cyanates to effect a pressure reduction seems to be 10 to 15 mg. Toxic manifestations and vascular collapse have occurred around 50 mg.

DISCUSSION

DR. EDGAR V ALLEN, Rochester, Minn. Will Dr Barker say a few words about the mechanism by which the cyanates reduce the blood pressure?

DR J W SCOTT, Lexington Ky. I should like to ask about the measurement of the level of cyanate in the blood.

DR. W B KOUNTZ, St Louis. There has been so much criticism on the use of cyanate in hypertension that I am glad to hear a paper that says it has value. I have used it in a large number of cases of hypertension and a satisfactory response has been shown in a great many. I have not used the size dosage that Dr Barker has and have not seen any toxic manifestations but have kept the dose well down. The routine has been to give it in courses of two weeks on and two weeks off. A reduction in the blood pressure has been noted.

DR. M HERBERT BARKER, Chicago. I do not know about the action of the cyanates. So far as I know, no work has been done to prove their action. The general attitude has been that it produces muscular weakness. All of the patients complained of fatigue. In this period of readjustment, patients may complain of weakness and feeling "as though they would like to hold their own eyelids open." Their legs may be so tired that they can hardly carry themselves around. That wears off and their full energy returns and they feel stronger than ever. So I do not feel that the muscle tone is the whole answer. It is not true of the muscle tone in the vascular tree, because these patients have not regained their strength if blood pressure is an index. An attempt has been made to show the good effect to be on the nerve structure or on the suprarenals but this has not been satisfactory to date. The method of determining the cyanates is very simple. When the cyanate is combined with iron it produces a tan or wine color, which is easily read in a colorimeter. Dr Kountz's point is a good one. His experience has taught him to give cyanates on alternate weeks, which is one way of being cautious. Unless these patients are smokers, the salivary cyanate level is very low. There is virtue in the cyanates if used properly.

Coronary Thrombosis—A Follow-Up Study

DR. WARREN B COOKSEY, Detroit. Fifty-three cases of coronary thrombosis seen in private practice since 1928 have been followed. Twenty-one of the patients or 39.6 per cent, are dead, while thirty-two, or 61.4 per cent are living. Of the patients who died, 71.5 per cent were above 60 years of age, with an average age of all patients who died of 63.4 years, while the average age of living patients is 54.2 years. In the living group, one patient is living at thirteen years ten are

living at six years, two at five years, five at four years, five at three years, two at two years, and seven one year after typical severe coronary occlusions. Of the living patients, 78.1 per cent have been restored to their previous occupation. Recent electrocardiograms of the living group show evidence of coronary disease in 90 per cent. The most frequent observations are RT changes, 56.6 per cent, cove negative T_1 or T_2 , 43.3 per cent, diphaseic T_1 or T_2 , 40 per cent, and a prominent Q_3 , 16.6 per cent. These data justify a much more hopeful prognosis for all cases of coronary occlusion in which the first six months has been survived.

DISCUSSION

DR. W. B. KOUNTZ, St. Louis. Has Dr. Cooksey used any vasodilator following coronary thrombosis?

DR. L. N. KATZ, Chicago. Coronary thrombosis is not always an inevitably fatal disease. As methods of diagnosis improve, earlier and milder forms become recognized. This is the merit of the four lead electrocardiogram. I recently saw a patient at Michael Reese Hospital with a stab wound of the heart in whom the lower part of the left descending branch of the coronary artery was tied at operation. The patient developed a serial electrocardiographic picture of myocardial infarct without any clinical evidence. In fact, as soon as he left the hospital he began doing hard manual labor without ill effect. As knowledge of the disease develops it will be found that coronary thrombosis ranges from extremely severe forms to what might be termed subclinical varieties.

DR. F. N. WILSON, Ann Arbor, Mich. I should like to make one or two remarks concerning the mortality in coronary occlusion. If one ties off a large coronary artery in a series of dogs, about half the animals die. The great majority of the deaths occur within the first twenty minutes and are due either to the onset of ventricular fibrillation or to contractile failure without any disturbance of the cardiac mechanism. I suspect that the majority of the patients who die as a result of coronary thrombosis are dead before the physician arrives. If death does not occur within the first half hour, the chances that the patient will survive are excellent.

DR. W. B. COOKSEY, Detroit. Concerning vasodilators, I take the attitude that one is struggling to maintain collateral circulation and that anything which will facilitate it is worth while. Whether anything is being accomplished by vasodilators I believe is hard to answer. In relieving angina pectoris they have certainly proved very satisfactory. I have used chiefly aminophylline, theobromine alkaloid or synthetic theophylline. Dr. Wilson's remarks are well taken. The mortality does vary. I would not say that, if I knew all the patients with whom I come in contact who later die of coronary occlusion, the mortality would be quite so good as it is. It depends on many factors. Much depends on the size of the vessel occluded, and it is of great importance what the patient does in the few days and weeks following the occlusion. One more interesting fact that perhaps I did not emphasize sufficiently, I believe that the older age group (60 to 70 year group) has less chance of surviving following a coronary occlusion than the younger group.

Clinical Study of Electrocardiograms in Pellagra

DR. HAROLD FEIL, Cleveland. These observations were made in thirty-eight cases of pellagra seen in the medical service at Lakeside Hospital. All cases were typical pictures of pellagra and alcoholic in origin with the exception of one boy, aged 15 years, whose diet had been inadequate. Electrocardiograms were made in all cases during the height of the disease and in most cases at weekly intervals during the convalescence. In twelve cases the phases of cardiac systole were studied by heart sounds and subclavian pulse records. In 60 per cent of the cases the electrocardiogram was normal. Of the remaining, there were the following abnormalities in the order of frequency: inversion of T_1 and T_2 , or both, 16 per cent, Pardee T (13 per cent), inversion or eversion of ST, large T in at least one lead and low voltage, 18 per cent. Electrical systole was slightly lengthened and likewise mechanical systole. The isometric phase was normal. The electrocardiograms in some instances returned to normal with recovery. Teleroentgenograms in several cases were normal. Pathologic study of the hearts coming to postmortem was normal. The electrocardiogram was abnormal in about one fourth of the cases of

pellagra, and electrical and mechanical systole are prolonged in most cases, suggesting that the heart is affected.

Stimulants of Bone Marrow in Hog Gastric Contents

DR. JOHN H. FOULGER, Cincinnati. Chemical and clinical studies of concentrates of hog gastric contents, carried out in association with the late Prof. Roger S. Morris, show that, in addition to the hematopoietic agent which Morris termed addisin, there is present a distinct chemical substance which, on intramuscular administration to patients showing a neutropenia, can cause a marked and often prolonged increase in the granulocyte count. The response is most pronounced in patients who are either resistant to massive doses of pentnucleotides or who have received smaller doses of pentnucleotides than are usually of therapeutic value. A single injection of 180 mg. of a crude preparation of the granulocytopenic substance of hog gastric contents has sufficed to produce a remission.

DISCUSSION

DR. FRANK J. HECK, Rochester, Minn. I am very skeptical about the efficacy of any of the preparations on the market at present for treatment of granulocytopenia. No untreated control series has been run, so far as I know, by any of the men reporting excellent results with the various therapeutic measures now advocated. Granulocytopenia is merely a condition that occurs in any one of a considerable number of diseases. Proper classification as to etiology is important. I should like to ask Dr. Foulger whether there was any history of drug use in the cases he is reporting.

DR. RAPHAEL ISAACS, Ann Arbor, Mich. I noticed that the total white count in some cases is about twice the total polymorphonuclears. I recall that the original work of Dr. Morris and his associates showed a neutrophilic increase. Since this substance was injected into the muscle, it could have acted on the muscle and produced a new substance similar to that developed during gastric digestion. The eosinophilia is suggestive of this.

DR. C. A. DOAN, Columbus, Ohio. I would like to ask whether any animal experiments together with study of the tissues have been made.

DR. L. G. ZERFAS, Indianapolis. The injection of fresh human gastric juice intramuscularly into a patient with pernicious anemia in relapse is without hematopoietic effect. When the gastric juice is stored in the icebox for two months or incubated for four hours at 40 C. however, definite reticulocyte responses occur. An increase in white blood cells also takes place at the same time. The same is observed when potent hematopoietic substances are fed by mouth or when they are injected. Dr. Helmer, Dr. Fouts and I have felt that the general bone marrow stimulation observed as a result of the injections of incubated gastric juice was due to some protein breakdown or to an actual blood destruction process and not to a hormone in the gastric juice. We have had no other experience with the white blood cell stimulating effect reported by Dr. Foulger. The lack of knowledge concerning the physiology of the bone marrow makes it extremely difficult for us to explain many of the responses observed.

DR. JOHN H. FOULGER, Cincinnati. I agree with the remarks about the lack of control. Nothing is known about the physiology governing the output of cells by the bone marrow. Patients with an extremely low white count are usually extremely sick. The clinician in charge is anxious to do something. The real object is to save the patient. I doubt whether in this type of case one will ever have scientific control and whether any methods of stimulating bone marrow are curative. Sooner or later the bone marrow reaches a state such that it will not respond to any treatment. I am perfectly agreed on our ignorance of the cause of spontaneous remissions in these cases, but in testing many substances of this type it is necessary to accommodate oneself to the material available. With regard to the action on muscle tissue of such injections, I think that the preparations used in most cases have been fairly pure chemically, much purer than liver preparations. Some of the concentrates used in the treatment of these cases have not been irritating in any degree. The possibility of the presence of trichina must of course be thought of in all work with swine products. But the preparations used were filtered

and therefore could not have contained trichina. Coming back to the work reported by Dr. Morris and his associates, it has been claimed that all their results were obtained because the concentrates of gastric juice acted on muscle. These claims might, I suppose, be accepted in the absence of further knowledge. But the most active preparations of addisin were made by a method that seemed to me as a chemist to have excluded all enzymes. They were made by esterification and extraction with ether. I do not know of any enzyme that can be subjected to the process used, and then extracted with ether. Preparations made in this way were the most active we have obtained in the production of hematopoiesis. With regard to animal experimentation, experiments are being conducted at present on the effect of this particular concentrate of the white cell count.

The Influence of Gastric Lavage on Familial and Nonfamilial Erythremia

DRS. HARRY OERTING and JOHN F. BRIGGS, St. Paul. Following the suggestion of Morris that erythremia may be the result of hyperaddisinism, the influence of gastric lavage on the erythremic syndrome was observed in erythremia of the familial and nonfamilial types. Lavage was done in each case from four to six times daily and the time of lavage varied from day to day. In nonfamilial erythremia, lavage alleviated the clinical symptoms and there was a marked improvement in the blood picture. In familial erythremia, lavage relieved the symptoms and prevented the usual increase in the blood picture. The material obtained from the nonfamilial erythremia lavages was placed untreated in the stomachs of patients with primary anemia and was effective in producing remissions. Evidence indicates that primary anemia and erythremia are antagonistic phenomena and that they represent states of an addisinism and hyperaddisinism. It is also suggested that in familial erythremia alterations in hemolysis are the factors producing the syndrome.

DISCUSSION

DR. LEON SCHIFF, Cincinnati. Several years ago I noted a marked drop in the red cell count in a patient with polycythemia vera and duodenal ulcer who had been lavaging his stomach daily as part of a Sippy regimen. This observation suggested the possibility of an excess of hematopoietic factor in gastric juice as playing a role in polycythemia and led to the suggestion of gastric lavage as a therapeutic measure in this disease. Since then I have treated two cases of polycythemia vera with repeated gastric lavage. The gastric contents were aspirated two or three hours after each meal for a period of two months. The patients were on a low purine diet, and an attempt was made to decrease and neutralize their gastric secretion by the use of belladonna, bromides and alkalis. No effect was noted on either the symptoms or the blood count. The failure to obtain a response does not disprove the existence of an excess of "intrinsic" hematopoietic factor as two months is a relatively short period, and at best only a fraction of total gastric juice secreted can be removed. It may require years for pernicious anemia to develop after total gastrectomy in spite of the established relationship of the stomach to hematopoiesis. As Dr. Briggs stated, the report of Wilkinson that an extract made from the liver in a case of polycythemia vera contained more antianemic substance than an extract obtained from normal liver is interesting and may have some bearing on this discussion.

DR. L. G. ZERFAS, Indianapolis. The observations reported by Wilkinson relative to the gastric juice may not bear any relationship to the etiology of polycythemia vera. The theory that polycythemia may be the result of a hypersecretion of the "intrinsic factor" in the gastric juice is intriguing. However, there is another point of view to consider which seems more plausible, namely, the relationship of anoxemia to the overproduction of red cells. It is common knowledge that there occurs in this disease extensive fibrosis and thickening of the walls of the arterial vessels. Dr. Reznikoff of New York has demonstrated the marked fibrosis of the bone marrow, which may in itself produce a sufficient degree of anoxemia in this tissue to cause an overproduction of red cells. Studies made at high altitude have already shown the relationship of the reduced oxygen supply to the increased number of red cells and hemoglobin in the peripheral circulation.

DR. W. B. COOKSEY, Detroit. About a year and a half ago when Dr. Morris first mentioned this possibility, I saw a case of polycythemia vera in which there was a count of eight million. At the same time I saw a case of aplastic anemia in which many kinds of treatment, including addisin, had been administered. The patient was a very intelligent man and wanted to take more addisin. As he was willing to pay for it, I trained my polycythemia vera patient to wash his stomach twice a day and deliver the contents to the other patient. This procedure was followed for four weeks with no benefit whatever to either patient.

DR. HOWARD L. ALT, Chicago. Were any determinations of the acid-base equilibrium made in these cases?

DR. S. M. GOLDHAMER, Ann Arbor, Mich. If one follows over a period of months the red cell count in cases of polycythemia vera, there is often a variation of more than three million cells. In the figures on the board, there is a variation of half a million or a million red blood cells, which amount would fall within the limits of error. Furthermore, if a patient with polycythemia does get an excess of addisin, all the red blood cells developed should be adult rather than young cells. Also, it has never been shown that liver extract can be given to patients in sufficient amounts to produce a constant reticulocytosis which can be maintained over a period of years as one sees in cases of polycythemia. As to the protective mechanism, when one gives a patient an excess amount of the "unknown" substance, intramuscularly or intravenously, in a few hours one can find a large amount present in the urine. It seems to me that in these individuals with polycythemia the body would take care of any excess substance produced.

DR. RAPHAEL ISAACS, Ann Arbor, Mich. I should like to suggest another interpretation of this material, which is that pernicious anemia and polycythemia are not opposites of each other. In pernicious anemia the factor that matures the red cells beyond the megaloblast stage is missing. Therefore the body tries to make red cells but can never mature them beyond that stage. The bone marrow is full of megaloblasts. If there was too much "maturing substance," the red cells would mature too fast. Instead of having too many red blood cells, the patient would have an aplastic anemia. He would mature all the cells and they would stop developing. Aplastic anemia is the opposite of pernicious anemia and not polycythemia.

DR. W. S. MIDDLETON, Madison, Wis. The experience at the Wisconsin General Hospital might be of interest. After this intriguing concept of the Cincinnati group appeared, a patient with polycythemia vera came in with 9,000,000 red blood cells. Gastric lavage was instituted twice a day and there seemed to be a brilliant response, the red cells going down to 6,500,000. Apparently the lavage was kept up too long for after six weeks the count went up to 9,000,000. I think this experience has been repeated by Farrar at Ann Arbor. We considered doing a partial gastrectomy if the remission in the blood picture was repeated after a period of rest and then renewal of gastric lavage.

DR. JOHN F. BRIGGS, St. Paul. No study has been made on the acid base equilibrium following lavage. This patient was followed for two or three years with counts two or three times a week and there was no marked variation in these counts. During the time before gastric lavage was started the reticulocyte count was at its lowest. The second patient is responding to lavage. Apparently the secret of the response is frequent lavage with complete washing of the stomach. Unless 700 cc. of gastric juice is expressed daily, a drop in the blood picture is not obtained.

Clinical Study of Idiopathic Thrombosing Disease (Thrombophilia)

DRS. KAARE K. NYGAARD and GEORGE E. BROWN, Rochester, Minn. A group of cases has been recognized and studied, in which there are episodes of thrombosis of the veins or of the arteries. Thrombosis in the vessels appears independent of intercurrent disease specific infection or operation. There is no demonstrable primary disease of the wall of the blood vessel. The primary disturbance, in some of these cases at least, seems to be of hematogenous origin, changes in the coagulability of the blood plasma, increase in the number of platelets and (or)

changes in the normal albumin-globulin ratio of the serum proteins. These changes appear with remission of thrombosis. In diagnosis, there has been confusion with thrombo-angitis obliterans. The group of cases considered represents, probably, a distinct clinical entity, which in the past has been designated idiopathic phlebitis or simple thrombosis of the vessels.

DISCUSSION

DR C. A. MILLS, Cincinnati. I should like to know whether these patients were tried on a low protein diet therapy and, if so, what effect it had. There seemed to be quite a period in which the thrombosing condition existed.

DR. EDGAR V. ALLEN, Rochester, Minn. The thesis of Drs. Nygaard and Brown is that there is a condition in which occlusion of arteries and veins is due solely or largely to intra-vascular coagulation resulting from an increased case of coagulation of the blood. This condition is different from the usual case of vascular thrombosis, in which the primary cause is in the wall of the vessels. Two questions are apparent. Why doesn't the thrombosis extend to involve the major portion of the blood vascular system, and why does it involve arteries chiefly when the slower flow in the veins is more conducive to thrombosis? A more logical explanation is that there is some localized vascular injury, which serves as a basis for thrombosis, which would not occur ordinarily. Support for the contention of the authors is offered by observations that the cases are bizarre ones clinically, that usual cases of chronic occlusive arterial disease do not show increased coagulation of the blood, and that microscopic examination of the involved vessels in the syndrome described by Drs. Nygaard and Brown does not show the usual inflammatory changes in the arteries and veins such as are seen in thrombo-angitis obliterans, or the degenerative ones such as are seen in arteriosclerosis. The clinician is greatly aided by the observations made by Drs. Nygaard and Brown as they explain bizarre types of vascular disease not satisfactorily classified heretofore.

DR. J. W. MOORE, Louisville, Ky. Has he had any instance of thrombosis in the pulmonary veins?

DR. KAARE K. NYGAARD, Rochester, Minn. We have not made use of any diet or any kind of therapy in an effort to change the coagulability factor. We have tried dyes. So far as we could make out, they have been of no value in changing the coagulability. These patients had fever at the time. In the first case that I reported a man aged 27, had fever for two weeks and then a subnormal temperature for another week, and a low leukocytosis. In one of these cases it was found that there was a thrombus in the pulmonary vein. We went over the cases from 1924 but none of them had any pulmonary emboli so I think the idea of the pathologist at the time was an occlusion in the pulmonary veins.

High External Temperatures, the Suprarenals,
and Body Relaxation

DR. C. A. MILLS, Cincinnati. The heat of the past summer has brought out in striking fashion the physiologic effects of high external temperatures. Widespread declines in blood pressure levels have been noted in all types of patients, with the average being around 30 per cent. Normal pressures have declined below 100 and hypertensive cases have shown just as marked falls. These heat effects would seem to differentiate between the sclerotic and spasm factors in hypertension, for, when real sclerosis was present, the fall in pressure was halted above the normal level. Many cases of hypertension without evident sclerosis fell to within normal limits. This demonstration of natural heat effects with the resulting evidences of body relaxation, clearly bears out what I have previously written as to climatic and weather stimulation, and the importance of this factor in metabolic and arteriosclerotic disturbances. Here lies the explanation of the marked differences between tropical regions of moist heat and temperate regions of great storminess in their relative severity and frequency of metabolic and degenerative diseases. Artificial moist heat might well be tried in northern winters in an attempt to mimic this relaxing effect of summer heat waves.

DISCUSSION

DR. E. P. McCULLAGH, Cleveland. In consideration of the suprarenal glands and their relation to body temperature, it is

interesting to reflect that in suprarenal apoplexy, as seen in children or occasionally following suprarenal operations, there is a very marked increase in body temperature as part of the clinical syndrome. There are two other striking features which accompany acute suprarenal insufficiency of this type, first, a peculiar sort of drowsiness, which gradually increases to coma but is quite distinct from the sort of mental change seen in Addison's disease, and, second, a rapid respiratory rate. I wonder whether these two phenomena associated with rapid failure of the suprarenal could be correlated in any way by Dr. Mills with the changes that he has been discussing.

DR. E. L. SEVRINGHAUS, Madison, Wis. There are two things of interest in the presentation of Dr. Mills. One is that there is a well recognized critical level above or below which there is failure to get maximum vasodilatation. That critical level seems to be about the body temperature. On the basis of this fact I have been using controlled heat for vascular disease of peripheral type and from its use there is apparently better circulation in the extremities. The other point is that Dr. Mills suspects that there is decreased heat production with high environmental temperature. There is good evidence in human and animal work showing that there is also a critical minimum of heat production by the body, which is at about 30 to 32 C. As one goes to higher temperatures there is an increase in heat production. If the critical temperature level is exceeded, I wonder whether he has evidence of decreased production in hot weather.

DR. CLARENCE F. G. BROWN, Chicago. Until more is known about the quantitative clinical measurement of the suprarenal and its action, shouldn't one think of this as the direct action of an external stimulus on the vegetative nervous system itself? This can set in play all the visceral reflexes necessary to produce the results described so well by Dr. Mills. Similar clinical pictures have been produced by changes in intrapulmonary pressures both in the dog and in man.

DR. C. A. MILLS, Cincinnati. There is good evidence, I think, of an actual change in the level of heat production depending on the external temperature to which the individual or animal must accommodate itself. We did not go into this phase of animal adaptation at Cincinnati because of scarcity of funds for the purchase of metabolism apparatus. However, workers in Belgrade (S. Gelineo, Institut de physiologie general de l'Universite de Belgrade) last spring sent me copies of recent papers of theirs in which were detailed the results of experiments covering this point. They found that animals adapted to a given temperature level showed a marked increase in heat production when the external temperature was lowered. Furthermore, the lower the temperature level to which the animal was adapted, the greater was the heat production increase when a further drop in temperature occurred. Animals adapted to 35 C, for instance, showed a much less marked increase in heat production when the environmental temperature was reduced 10 degrees C than did those adapted to 25 C. The more active the metabolism of the animal, the greater seems to be his response to chilling, and the differences found are quite striking. This is what I felt sure was happening in the response of man and animals to drops in environmental temperature. I have had many scientists suggest that such response was mainly vasomotor, shifting the blood away from the cooled surfaces so as to maintain body temperature. Such vasomotor reactions I feel to be of minor importance in the body adaptation to chilling, changes in heat production playing a far more important role in this respect. I do not know just how the symptoms of suprarenal apoplexy would fit into the picture of adaptation as I have presented it. In some such cases the symptoms much resemble the exhaustion of heat prostration which I have attributed to loss of function in the suprarenal cortex. Other cases are more like heat stroke, with a complete derangement in the temperature adaptive mechanism. So far as I know, the suprarenals cannot be entirely separated from the vegetative nervous system. The talk recently given by Dr. Dale at Indianapolis brought this fact out in striking fashion. The proof seems almost complete that epinephrine or a very similar substance is liberated by impulses arriving at the sympathetic nerve endings and that it is this chemical activator which transforms the nerve impulse into tissue stimulation. I have long felt that suprarenal activity played some

definite part in the tissue response to autonomic stimulation, and now Dr Dale seems to have the detailed explanation of why this should be so. It is easily seen, then, how difficult it becomes to separate suprarenal function from that of the vegetative nervous system.

Involution of the Thyroid Under Prolonged Injections of Pituitary Thyrotropic Hormone

DR PAUL STARR, HELEN PATTON and RICHARD BRUNER, Chicago. Following the work of Collip, Friedgood and others, the thyroid gland of the dog and guinea-pig have been studied during prolonged injections of a solution of sheep anterior pituitary gland substances. The initial hyperplasia gives way to involution during these injections. Histologically, the gland does not appear to be exhausted of secretion. [Photomicrographs of such glands were shown. The important problem of the mechanism of this involution, whether induced by action of some other hormone or simple recovery after neutralization of the injected material by an antibody, were discussed.]

DISCUSSION

DR E. P. McCULLAGH, Cleveland. Were the metabolic rates determined in these animals and if so, did the levels following treatment fall to below normal? If it is true that by the Janssen method a preparation of thyrotropic hormone can be made that will be protein free, I wish to suggest that it might be possible to free such a hormone from protein substances sufficiently to preclude the possibility of immunity as the cause of antihormone effect.

DR GEORGE M. CURTIS, Columbus, Ohio. Was any investigation made of the iodine content of the glands?

DR E. L. SEVRINGHAUS, Madison, Wis. I think that the authors would like to know that there is some analogous work on the ovary at Madison. Hisaw has been carrying out that work after the plan of Collip and has transferred a passive immunity to gonadotropic extracts to other animals. The authors have described the refractory period that comes after active stimulation as Hisaw found it in the ovary. This refractory period occurs after a few weeks of treatment but disappears after a few weeks' rest without continuous injections. These changes do not seem like immune reactions.

DR PAUL STARR, Chicago. In answer to Dr McCullagh, we are working on guinea-pigs and do not find subnormal rates in the involutional period. We have not made any iodine studies, although such have frequently been made abroad both on glands and on blood. The Janssen material, is an impure protein precipitate. I doubt whether one could use its supposed freedom from proteins as an argument against immune bodies. Dr Collip reports that agglutinins cannot be obtained. It is interesting then that serum taken from these animals will inactivate the original hormone.

Calorigenic Action of Extracts of Anterior Lobe of Pituitary

DR W. O. THOMPSON, DR S. G. TAYLOR III, DR PHEBE K. THOMPSON and L. F. N. DICKIE, Chicago. The subcutaneous administration of extracts of the anterior lobe of the pituitary produced an increase in basal metabolism in twenty-four of thirty-nine patients of various types including three with hypopituitarism, seven with nontoxic goiter, three with low basal metabolism of unknown cause, four with typical myxedema, nine with mild myxedema (three of these had a nontoxic goiter) and five with exophthalmic goiter. The increase in metabolism was only temporary in spite of prolonged administration of the extracts, the greatest length of time that the metabolism was affected being about two months. No increase in metabolism was observed in the patients with typical myxedema (more data are needed to establish this point), but a well marked increase occurred in the patients with mild myxedema. During the injections in the patients with exophthalmic goiter, mild cases of the disease became moderately severe ones. This increase in the severity of exophthalmic goiter naturally raises the question of the role of the pituitary in the disease.

DISCUSSION

DR PAUL STARR, Chicago. Possibly the most valuable application of this material might turn out to be its use in the stimulation of large colloid goiters with depressed thyroid

function. The physiologic work suggests that one may be actually producing in the patient an antimechanism, which in the end may increase the disturbance for which treatment was given.

DR CECIL STRIKER, Cincinnati. I should like to ask whether, after the metabolism has dropped to normal and the thyroid is apparently exhausted, if one gives thyroid extract, the metabolism rises? If the thyroid is exhausted and one increases the pituitary, does one get another rise in the metabolism?

DR W. O. THOMPSON, Chicago. We are not drawing conclusions from this work about the treatment or about the mechanism of production of exophthalmic goiter. We are merely presenting a few observations, the precise nature of which still remains unsolved but which possibly can be explained on the basis of stimulation of the thyroid by the pituitary. I do not believe these extracts are suitable for routine clinical use at present because of their temporary action. It is possible that the active principle of the anterior lobe is linked to a complex molecule and that immunity to this complex substance results in the development of immunity to the active principle. If such a point of view should prove to be correct, isolation of the active principle may result in a substance that produces calorigenic action indefinitely.

Relation of Thyroxine to the Metabolism of Tissues

JAMES C. DAVIS, PH.D., and A. BAIRD HASTINGS, PH.D., Chicago. Experiments have shown that total thyroidectomy results in decreased metabolism of the excised striated muscle of mice. Conversely, the injection of thyroxine in mice with and without previous thyroidectomy increases the excised tissue metabolism. Attempts to demonstrate an increase in tissue metabolism by the addition of thyroxine to the excised tissue of mice *in vitro* have given negative results. It has been found, however, that by utilizing a technique for keeping the excised frog heart alive for several days a marked increase in the metabolism of the frog heart may be demonstrated fifteen hours after the addition of thyroxine to the nutrient fluids *in vitro*. This result has been confirmed on the heart of the limulus, with and without its ganglion.

DISCUSSION

DR WALTER M. BOOTHBY, Rochester, Minn. It is interesting that the latent period is the same in these experiments as it is in man.

DR GEORGE M. CURTIS, Columbus, Ohio. As a corollary to this work I should like to present results concerning the blood iodine after total thyroidectomy. It maintains a level of about one-third normal. The blood iodine has been separated into alcohol soluble and alcohol insoluble portions. Presumably the alcohol insoluble portion is the thyroid hormone. After total thyroidectomy, this portion, about two thirds of the blood iodine, falls out, and only about one third of the normal blood iodine content remains.

DR A. BAIRD HASTINGS, Chicago. I should like to emphasize that this would not be a good way of assaying thyroxine, because it takes a large number of experiments and there is a good deal of scattering in the determinations. It is only by doing a large number and waiting quite a long time that we are able to show the effect of thyroxine on tissues *in vitro*.

Metabolic Studies in Osteoporosis

DRS MILDRED ADAMS, WALTER M. BOOTHBY and ALBERT M. SNELL, Rochester, Minn. A prolonged metabolic study was made on a patient with a senescent type of osteoporosis, to determine the ability of such a subject to absorb calcium and phosphorus. For about five months the patient was on a constant, weighed and analyzed diet with the addition of known amounts of tribasic calcium phosphate or calcium lactate, with and without viosterol. During the control period the subject definitely lost calcium, although there was a slight, positive nitrogen balance. It was possible to prevent this loss of calcium with either calcium phosphate or calcium lactate, although, when given in equivalent amounts without viosterol, calcium lactate appeared to be more efficient. Viosterol increased the retention of calcium after feeding of calcium phosphate but had little influence on the retention after feeding of calcium lactate.

Current Medical Literature

AMERICAN

The Association library lends periodicals to Fellows of the Association and to individual subscribers to THE JOURNAL in continental United States and Canada for a period of three days. Periodicals are available from 1925 to date. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 12 cents if two periodicals are requested). Periodicals published by the American Medical Association are not available for lending but may be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.

Endocarditis Caused by Diphtheroid Bacillus (Pleomorphic Streptococcus)—Foord and Stone present a case of subacute bacterial endocarditis having a typical clinical course and showing typical postmortem observations. From the blood on four occasions during life and from the blood and heart valve after death a diphtheroid bacillus was recovered in pure culture. Smears and sections of the heart valve revealed large numbers of the same organism with no other organism present. The serum of the patient obtained after death agglutinated the organism in high dilution. On liquid mediums streptococcal forms were produced, but only bacillary forms were found on blood agar. The case well demonstrates that diphtheroid bacilli in blood culture may be of vital importance and are not always simple contaminants. The entire clinical and pathologic picture presented by this patient and the bacteriologic studies point strongly to the view that the organism obtained is only a stage in the life cycle of a green producing streptococcus. The authors suggest that all strains of diphtheroid bacilli obtained from human cases of infection be cultured on appropriate mediums in order to demonstrate their relation to streptococci.

Typhoid Paratyphoid Therapy in Idiopathic Epilepsy—Antell treated six epileptic patients with intravenous injections of typhoid paratyphoid vaccine as a means of producing fever. Of these five were children and one was a young adult. The results in all the children thus far have been good. There

were no recurrences of seizures after periods of from seven months to two years from the institution of treatment. The one failure was in the case of the young adult. The author states that the possible advantages of this method of treatment over that of the ketogenic diet would seem to be that it is shorter, simpler and easier to carry out. With the first patient, it was used in conjunction with the ketogenic diet. The seizures were stopped completely, whereas it was impossible to do this with the ketogenic diet alone. The technic employed and followed closely was that described by Sutton in the treatment of chorea minor. New York City Health Department typhoid-paratyphoid vaccine was given intravenously at the elbow if possible or, in rare instances, in the jugular vein.

Control of Rickets—Barnes protected thirty-two normal infants against rickets from November or December to April on 50 units of vitamin D given as a concentrate in milk. Six infants entering the study with slight roentgenographic signs of rickets showed progressive improvement on 50 units of vitamin D in milk a day. Since the rachitic lesions were slight, the healing processes were not striking, but they were nevertheless definite when traced throughout the series of roentgenograms. In no case did the patient grow worse during the study. A control group of twenty-five infants without antirachitic treatment during the winter were examined roentgenologically in April. Fourteen, or 56 per cent of these, showed active rickets, the remainder being normal. It is shown that for comparison of the various forms of vitamin D the ratio 40:240 for the vitamin D of irradiated milk and the vitamin D of cod liver oil does not hold. When both are given in milk the required units are approximately equal. Considering the relatively small number of infants, the error of biologic assay and the difficulty of quantitative clinical evaluation, it is not safe to say that one differs from the other. A standardized clinical procedure is necessary in order to make satisfactory quantitative comparisons of various antirachitic substances.

Neutralizing Value of Various Substances in Poliomyelitis—The experiments of Toomey on guinea-pigs show that serum obtained from Rosenow as well as commercial serum manufactured according to his method contained neutralizing bodies against the toxic factors present in the stools and urines of patients with poliomyelitis. Normal horse serum was equally good when used as a neutralizing agent against the same toxic factors present in the stools of patients with poliomyelitis. Serum from patients convalescing from poliomyelitis when injected intraperitoneally into guinea-pigs prolonged the life of the animals if they subsequently received injections of suspensions of coli paratyphoid organisms. In the dosage used, it did not prevent the ultimate death of the animal. The pathologic reaction of the cord was the same after injections of coli paratyphoid organisms as it was after injections of infantile paralysis stool emulsions. The spleen, and not the suprarenals, was the organ most involved after injections of coli paratyphoid organisms. Horse serum when injected intraperitoneally into guinea-pigs prolonged the lives of the animals that later received injections of lethal doses of coli paratyphoid suspensions. Unlike the animals which received injections of stool emulsions from patients with poliomyelitis, the pathologic reaction was most obvious in the spleen.

Roentgenologic Study of Tuberculosis of Larynx—

Taylor and Nathanson believe that laryngeal tuberculosis is a frequent concomitant of the malignant type of pulmonary tuberculosis and that it occurs often enough to warrant routine roentgen studies of the neck, in view of their diagnostic value. They obtain a sagittal view and can therefore gauge the height and width of the lesion as well as the presence of a subglottic extension. Small intraventricular lesions, which may be missed on mirror examination, are demonstrable on the roentgenogram. Small lesions situated deep in the interarytenoid area are not detected on the roentgenogram. Roentgen examination gives a permanent pictorial record of the location, extent and progress of the lesion. It is essential to have at least two roentgenograms of the larynx—one taken at rest and the other during phonation in addition to the roentgenoscopic study.

Varix of Pulmonary Vein—Neiman reports a case of varix of the pulmonary vein. The patient entered the hospital because of a sudden paralysis of the left arm and left leg. Clinically the signs and symptoms pointed toward an intrapulmonary lesion (cyanosis with some difficulty in breathing). The roentgen examination of the chest revealed a well circumscribed lobulated tumor-like shadow of even density occupying the upper lobe of the left lung. This shadow fused with the heart and diaphragm in the postero-anterior view of the chest. Roentgenoscopically it was possible to separate this tumor from the heart shadow and to show that it had no relation to the ascending aorta. These, with the conditions found on clinical examination and the fact that comparison with a roentgenogram taken three years ago showed no change in size or shape, suggested a benign tumor of the lung. The mass was too well circumscribed and of too long duration to be a primary carcinoma of the lung. It was not in the mediastinum at roentgenoscopy, therefore a mediastinal tumor could be excluded. Since the shadow that the pulmonary varix casts on the roentgenogram is sharply circumscribed in character, it serves to distinguish it from conditions that are of an inflammatory genesis. Tuberculous lesions and abscesses may be distinguished from this condition because of the presence of the irregular peripheral inflammatory infiltrations in the former. The two conditions that resemble pulmonary varices are chondroma and solitary echinococcus cyst of the lung. However, since echinococcus cysts and chondromas are the most common benign tumors of the lung, the problem of diagnosis would rest in differentiating these conditions from pulmonary varix. As regards the periphery, the pulmonary varices are invariably nodular. The chondromas are similarly nodular, even though these irregularities may be slight while the echinococcus cyst is either perfectly smooth or presents slight inflammatory infiltrations in the immediately adjacent lung tissue. Frequently present in chondromas is the patchy, irregular distribution of lime salts, due either to simple calcification of the cartilage matrix or to true ossification. Calcification of the laminated chitinous lining membrane of the echinococcus cyst is occasionally present but is a more uniform process. In pulmonary varices it has been observed in small amounts. If the nodular periphery is present on the roentgenogram together with symptoms of cyanosis, dyspnea, cough, clubbing of the fingers or

toes and intermittent hemoptyses, with an absence of serologic and clinical evidence of echinococcus infestation, one should think of a pulmonary varix.

Multiple Spontaneous Idiopathic Symmetrical Fractures—Milkman describes a skeletal disease that is progressive, fails to respond to medication and may end fatally. He presents a case history, with reports of serial roentgen examinations over a period of eight years with postmortem observations. The characteristics of the disease are the disturbance in gait, pains in the back and peculiar multiple symmetrical involvement of the skeleton. The characteristic roentgenographic appearance is bands or zones of increased transparency seen throughout the involved bones of the skeleton. They are multiple and symmetrical. In the author's case, forty-three fractures occurred. A differential diagnosis may be made between this disease, late rickets, osteomalacia and fragilitas ossium. Pathologists differing in their interpretation of the microscopic appearance show the limitation of bone pathology in its ability to differentiate obscure osseous changes. The parathyroids are not involved so far as pathologic study is able to determine. The etiology is unknown. The postmortem observations of increased vascularity at the transparent zones suggest some trophic disturbance. The author states that, while it may be a worthy aim on the part of the pathologist to try to unite diseases of the bone into certain distinct groups, as von Recklinghausen, Looser, Schmidt and Wilton, the scientific attitude is first to separate the different entities into definite, distinct, individual diseases before grouping them under one disease entity.

Radiation Treatment of Carcinoma of the Cervix—

Healy and Arneson changed their usual plan of external irradiation with x-rays in twenty-five cases of squamous epidermoid cancer and one case of adenocarcinoma (all involving the cervix) in order to increase the amount of effective radiation given to the pelvic field adjoining the cervix, with the thought of controlling the disease in advanced cases for a longer period and possibly thereby to increase the proportion of permanent cures in such cases. The dosage delivered was 200 roentgens to each of two pelvic fields daily for a total of from 2,000 to 2,400 roentgens, without severe local or constitutional reactions. Clinical and histologic evidence of regression of the cancer in the cervix indicated that regression might also be reasonably expected in the disease in the parametrium for this amount of external roentgen irradiation. It would seem possible through these observations to plan a roentgen pelvic cycle that will deliver a tissue dosage adequate for control of cancer in the parametrium and outlying pelvic field without severe damage to normal structures. The authors believe that the opportunity offered to observe the coincident changes in the primary lesion may be utilized to advantage to follow the effects taking place in the parametria. Radium, however, should always be used for treatment of the primary lesion. In the earliest cases, with a small lesion limited to the cervix and without gross enlargement of the cervix, the radium treatment should be carried out before the roentgen cycle is given.

Protective Power of Yellow Fever and Dengue Serums Against Yellow Fever Virus—Snijders and his associates discuss the hypothesis that under special conditions dengue might provoke a certain immunity to yellow fever. A more sensitive adjustment was devised in Theilers as well as in Sawyer's mouse protection test in order to avoid the risk of missing moderate and lower degrees of immunity. The modifications applied to the technic are described. As a control for the technic five serums of former yellow fever patients were

examined By Theiler's method a distinct protection could be demonstrated in all cases, by Sawyer's method protection was evident in three cases The examination of the serums of five assistants working more or less regularly in the yellow fever laboratory revealed a weak protective action in two of them, both by Theiler's method and by the modification of Sawyer's test Considering that these two persons came into the most intimate contact with the yellow fever material, it is believed that they must have had mild (abortive) attacks of yellow fever at some time in the past The serums of twenty volunteers, who had been experimentally inoculated with virus of Sumatran and Javanese dengue, were tested by both methods, in several instances the tests were repeated Despite the sensitive adjustment of the tests, a protective action against yellow fever virus could not be demonstrated A comparison of the immunity in dengue and in yellow fever indicates that in dengue the immunity shows considerable individual variation with regard to intensity and duration, and specific antibodies cannot be demonstrated in the serum In yellow fever the immunity is almost absolute and antibodies are almost always present in the serum in high concentration

Esophagoplasty for Stricture of the Esophagus—Ochsner and Owens feel that anterotheracic esophagoplasty should be used only in cases of absolutely impermeable benign stricture of the esophagus or in cases of carcinoma in which the tumor has been extirpated The best results have been obtained in those cases in which the operation has been accomplished by using a segment of colon and those in which a newly formed esophagus has been constructed out of a loop of jejunum and a skin tube In mobilizing a jejunal loop the attempt should never be made to secure a loop of such length that the blood supply of the intestine will be in jeopardy This has been responsible for the high incidence of failure and fatalities in the jejuno-esophagoplasties in which an attempt was made to form the esophagus entirely from the jejunum The first stage of the jejunoentero-esophagoplasty should consist of the mobilization of the jejunal segment This should be brought up through the lesser sac, completely mobilized, and the distal end anastomosed to the stomach care being taken not to have a dependent loop The proximal end should be brought up through a skin tunnel anterior to the thorax The upper end of the jejunum which is brought out through a small transverse incision is sutured to the skin edges without the intestine being opened The second stage should consist of the formation of the skin tube and the immediate completion of the junction between the skin tube and the jejunum This is accomplished by extending the lateral incision for the formation of the skin tube down and round the jejunal opening In this way a flap is produced which can be mobilized upward

to be anastomosed to the skin tube, covering over the opening of the jejunum Following this, the newly formed skin tube, the anastomotic site and the defects produced by the mobilization of flaps are covered by mobilizing skin flaps on either side Relaxing incisions are necessary Sufficient time is allowed to elapse between completion of this stage and the third stage of the esophagoplasty for the wound to heal completely As a third stage the cervical esophagus is mobilized after a curved incision has been made, the incision passing along the anterior border of the sternocleidomastoid to a point just above the clavicle and then coursing laterally The esophagus is mobilized well into the mediastinum The upper end of the previously formed skin tube is freshened by a transverse incision, and the skin forming the lining of the tube is separated from the skin covering it The esophagus is mobilized well down into the mediastinum, doubly clamped by means of right-angled clamps and divided transversely The lower end is closed blindly by means of inverting sutures The upper end is brought up into the wound and the distal segment of the upper end is invaginated into the upper end of the skin tube The suture of the esophagus with the skin tube is accomplished by interrupted sutures passing through the subcutaneous tissue of the skin tube and barely catching the wall of the esophagus, care being taken not to penetrate into the lumen of the esophagus or to pass through the epidermis of the skin tube In this way salivary secretions are discharged into the lumen of the skin tube without any danger of their coming in contact with the suture line The skin flap is then replaced over the suture line, after a drain has been placed in the mediastinum Because of the possibility of mouth contamination, Vincent's infection should be looked for, and, even if it is not found, it seems advisable to give neosarsphenamine as a prophylactic procedure

Chronic Empyema—Martin believes that the cause of chronic pyogenic empyema lies in the reaction of the tissue to repeated slight infection of the pleura that such infection can be avoided by careful supervision of the treatment of the empyema cavity during the subacute stage, that a secondary operation with the removal of rib, and free drainage, will prevent extensive later operations, that when chronic empyema has developed surgical measures result in the starting of healing and the gradual obliteration of the cavity by making to some extent the rigid walls yielding, and finally that the residual thickened pleura resolves and becomes thin when the cavity is obliterated

Postoperative Wound Complications—In 9,155 general surgical procedures Eliason and McLaughlin observed 351 imperfect wounds, an incidence of 3.81 per cent Reduction of the amount of catgut under the subcutaneous tissue has been the most important factor in reducing the incidence of serum collections Contamination of the wound by infectious material handled at operation is one of the most frequent causes of superficial wound infection Drainage of the superficial layers of all wounds in which soiled material is handled will materially reduce the incidence of wound infections that do not interfere materially with convalescence 'Wide open' drainage with adequate separation of the wound edges is the most logical and satisfactory method of handling a wound infection No effort should be made to close amputation stumps following operations for infected diabetic gangrene in which pretibial edema, extending halfway to the knee, is demonstrable A definitely stormy postoperative course usually precedes the development of a wound rupture This was true in 88 per cent Wound disruption is usually observed between the fifth and eighth postoperative days, 80 per cent being diagnosed during this period The treatment of ruptured wounds with packing and adhesive straps is the safest method for the patient Peritonitis is the most common cause of death following wound disruption

Abdominal Wall Defects Following Appendicectomy—In 700 cases of appendicitis operated on through an incision in the right lower quadrant of the abdomen, Carlucci found that eighty-three, or about 12 per cent, had some postoperative abdominal wall defect These ranged from a simple weakness to hernias involving the whole length of the incision The value of accurate and repeated follow-up examinations is defi-

nately brought out by a study of this type. It is well demonstrated that cases in which the operation has been performed through a split rectus incision are followed by approximately twice as many defects as the intramuscular ones. It is also proved that the defects are about double in men as compared to women. Respiratory complications following the operation apparently have no bearing on the development of these weaknesses. In cases of appendical abscess in which the abdominal wall was not sutured or was only loosely approximated, many incisional hernias followed. On the other hand, fecal fistulas alone did not seem to produce any defect. Pregnancy and parturition even in cases in which drainage has been done apparently did not cause the incision to give way. That weaknesses and even hernias disappear as time goes on was well brought out. The records also proved that hernias could develop suddenly a year or more after the original operation. Only thirty-two were classified as incisional hernias. It is the author's impression, however, that a fair number classified as bulges are hernias with a large opening. In conjunction with this thought there is the possibility also that some of the bulges may be incomplete disruptions of the wound, that is, the external oblique fascia or anterior sheath has held, but the peritoneum and the overlying muscle have given way. To clear up this point it seems that more care should be given to the description of the pathologic changes found at operation when these defects are repaired.

Action of Epinephrine on Normal Eye—Howell states that the instillation of a 2 per cent solution of epinephrine into the conjunctival sac of the normal eye is usually, though not always, followed by a reduction in the intra-ocular tension. The drop in pressure may occur within one hour, but in most cases it is not obtained until later. A similar lowering of tension, though of much less degree, may be seen in the opposite eye. Mydriasis usually occurs within one hour and disappears within twenty-four hours. Following dilatation of the pupil of the normal eye, there is no tendency toward a sustained or material increase in the intra-ocular tension. Absorption of epinephrine from the ocular conjunctiva may produce systemic effects in susceptible persons. Solutions of epinephrine, since they do not produce an increase in intra-ocular tension, are a suitable mydriatic for use in studies of the fundus and media of eyes in which atropine or its derivatives might be dangerous.

Unilateral Ophthalmoplegia Totalis—Levitt reports the case of a woman, aged 20, who complained of left-sided headache and other symptoms referable to loss of motility and paralysis of accommodation of the left eye. Ocular examination revealed moderate ptosis, almost complete ophthalmoplegia totalis and slight exophthalmos of the left eye and a bilateral corneal hypesthesia. General physical and neurologic examinations and laboratory studies yielded negative results. Roentgenograms of the skull served to localize a calcified parasellar neoplasm on the left side. Operation disclosed a tumor at the junction of the left sphenoid ridge and the anterior clinoid process. Microscopic examination showed an osteochondroma with secondary changes. The tumor was probably derived

from the sphenoid bone. The ocular changes were the result of compression of the trunks of the third, fourth, first division of the fifth and the sixth cranial nerves coursing in the left cavernous sinus. Two months after operation the upper lid of the left eye returned to a normal position, and the functions of the external and internal rectus muscles were partly restored. The case represents an early type of basal intracranial tumor and illustrates the clinical syndrome of the external wall of the cavernous sinus in a pure form without masking features.

Acute Pancreatitis—Koster and Kasman cite twenty-two cases of acute pancreatitis with a total mortality rate of 22.7 per cent. Seven of the cases presented the typical picture of a sudden onset of severe epigastric pain followed by continuous vomiting and associated with prostration and cyanosis. In two cases presenting a similar picture there was an indefinite previous history of a condition simulating gastric ulcer, which was diagnosed as such. In another case diagnosed as acute pancreatitis accompanied by obstruction of the common duct by calculi and cholangitis of a duration of two weeks there was no shock or cyanosis, but the patient was deeply jaundiced. The remainder of the cases presented a less precipitous onset, which was suggestive of acute disease of the biliary tract. Attention is drawn to the fact that this last group of cases occurred most commonly in persons less than 36 years of age. It is suggested that in making the diagnosis acute pancreatitis should be suspected in every case presenting a history and symptomatology suggesting an acute exacerbation of disease of the biliary tract. Immediate and complete operation, which

includes cholecystectomy if the gallbladder is diseased or contains calculi, probing of the ducts to assure freedom from calculi or to allow for their recognition and removal, drainage of the biliary tract and examination of Wirsung's duct, in addition to treatment of the pancreatic lesion and the associated peritonitis, is advocated.

Therapeutic Use of Concentrated Antistreptococcus Serum—Sheplar and her associates treated twenty-six patients with the special concentrated antistreptococcus serum of the laboratory of the New York State Department of Health. There were five patients with generalized or metastatic infection without a clinically recognizable port of entry. These patients were brought under observation in the hospital after invasion of the blood stream had taken place. It is uncertain whether the site of the initial invasion could or could not have been recognized at an earlier time. The ages of the patients ranged from 2 weeks to 5 years. In the first case the first dose of serum was administered two days after a blood culture was recognized as positive. This was on the day before death at a time when meningitis must have already been present, according to necropsy. The second patient became ill with fever and the serum was administered ten days later when the blood culture taken two days before had shown positive growth. Necropsy revealed an acute vegetative mitral endocarditis with associated septic complications. In the fourth case the serum treatment was initiated eight days after the positive blood culture was taken and four days after the recognition of meningitis. In the third case, seven days after an operation for osteomyelitis the surgeon asked for the assistance of bacteriotherapy because of the impression that the disease was due to the staphylococcus. When the bacteriologic studies disclosed the true etiology, the streptococcus serum was administered in two days. There was a moderately severe serum rash four days later, but in other respects the behavior of the patient left little to be desired for nearly a month. The fifth patient had already suppressed the original invasion of the blood stream. The serum was employed as a safeguard against lighting up a streptococcal infection still persisting in the arm. The actual result was all that had been desired. Whether the patient would have done as well without the serum remains undetermined. In the authors' experience specific bacteriotherapeutic measures are most often instituted after too much delay. Their first, second and fourth cases represent examples. In the third case the earlier administration of the serum came about through a misapprehension. The bacteriologists were called in consultation in the hope of treating a staphylococcal infection with bacteriophage and, once this contact with the patient had been made, the early administration of streptococcus serum became possible. The authors conclude that, in vegetative endocarditis due to the hemolytic streptococcus and in meningitis coupled with bacteremia due to the same organism, the therapeutic use of antistreptococcus serum, in their hands has not been successful.

Agranulocytic Leukopenia with Multiple Peripheral Neuritis—Scully reports a case of agranulocytic leukopenia in which multiple peripheral neuritis developed during the course of the disease. There was no history of the use of any barbiturate and amidopyrine preparations. Pentnucleotide was used in the treatment of the neutropenia because of the favorable results that had been reported by Jackson and his associates and because of the lower mortality rate that was noted by Doan in comparison with other methods of treatment. The case presented the typical appearance of an agranulocytic angina but was unusual because of the complicating multiple peripheral neuritis. The marked inflammation of the throat was evidently the source of the toxins that produced the neutropenia while at the same time affecting the peripheral nerves. It is possible that if the condition had been recognized earlier and treatment instituted at that time, the damage to the peripheral nerves might have been avoided.

Chronic Cicatrizing Enteritis—Cushway presents a brief review of the literature of so-called "infectious granuloma" together with recent reports of this condition under the name "regional ileitis" and "cicatrizing enteritis." It seems to him that the term "cicatrizing enteritis" describes this condition best. Three cases are reported, two of which have been proved by definite pathologic changes. The third case is doubtful as to pathologic classification but showed the clinical and roentgenographic observations of "cicatrizing enteritis." The author believes that this pathologic condition may occur with a fair degree of frequency. The diagnosis can be made preoperatively only from roentgenologic studies. Crohn Ginzburg and Oppenheimer, in isolating this condition from the confusion of benign inflammatory lesions, have demonstrated a new disease entity. Harris Bell and Brunn have further clarified the situation by suggesting what seems to be a more descriptive term. The disease occurs mostly in young adults with symptoms of ulcerative colitis. Often these cases may be mistaken for appendicitis and operation may be performed. The disease eventually leads to obstruction of the small intestine with characteristic symptoms of obstruction. The physical observations are those of a tumor mass in the region involved with quite commonly the formation of a fistula. There is no definite known etiology. The pathology is constant both macroscopically and microscopically. The disease is benign and is most commonly found in the terminal ileum. The author hopes to stimulate an interest in this pathologic condition so that the roentgenologist will be on the alert and ready to recognize it.

Precipitinogenic Action of Human Plasma and Its Constituents—Hektoen and Welker found that the intramuscular injection of human plasma or human serum into rabbits, especially when absorbed by aluminum hydroxide, results in a production of specific precipitins which may be continued for months. The precipitin reaction of human plasma or serum appears to result from the single or conjoint action of individual specific precipitins against the various antigens in the plasma or serum.

Relation of Morphology to Virulence of Diphtheria Bacillus—During the course of the routine examination of 592 nose and throat cultures for virulent diphtheria bacilli, Jarema and Smith observed the following relationship between the morphology and the virulence of the organism. A greater percentage of virulence was obtained from mixed cultures of the diphtheria bacillus than from cultures of pure types. Cultures of diphtheria bacilli that were morphologically of the BT type, that is, bacilli which showed a tendency to bulge at one or both poles or anywhere along the body of the bacillus, were always found by inoculation of animals to be virulent. Of the virulent strains of diphtheria bacilli isolated, 59 per cent were of the BT type. Very distinct types of BT—a meta-chromatic granular bulging type and a blue mixture bulging type—may be considered virulent without the inoculation of animals. The elimination of the inoculation of animals with the BT type of the diphtheria bacillus would result in a saving of time and material. A clinical correlation was found between the presence of the BT type and the severity of the course of the disease in patients. Repeated virulence tests on cultures from diphtheria carriers and from patients with clinical diphtheria showed an apparent definite relationship between the morphology and the virulence of the diphtheria organism.

Cultural and Agglutinative Relationships of Intestinal Streptococci—According to Torrey and Montu, no specific serologic type of enterococcus or diplostreptococcus was found associated with the lesions of nonspecific ulcerative colitis. Although one or more serologically related groups may be demonstrated by agglutination tests among enterococci isolated from the intestine showing structural changes, members of such groups show differences in antigenic constitution as revealed by reciprocal agglutinin absorption inconsistencies. No correlation is apparent between fermentative activities, resistance to heat and other biologic characteristics of enterococci and serologic relationships. Micrococcus zymogenes is a variant of the enterococcus. Strains of enterococci serologically related to the type reported by Saunders as specific for gastric and duodenal ulcers were found in the intestine but more frequently in patients showing intestinal lesions than in normal adults.

The Etiology of Stone—Joly, in his discussion of the etiology of calculus, believes that the hypothesis that stone is a deficiency disease is the most plausible and probable that has been advanced. It not only explains all the principal features of the condition known today but also gives a reason for the changes in its incidence during past years. He believes that the vitamin starvation acts primarily on the renal epithelium and through it on the colloid mechanism of the urine and that, once this mechanism is deranged, formation of stone must follow as a direct result of the laws of physical chemistry.

Calculus Anuria in Acquired Single Kidney—Herman and Greene discuss calculus anuria occurring in single kidneys of surgical origin. The literature of the last five years contains reports of nineteen cases, to which the authors add four personal cases. The nephrectomized person, with few exceptions is in little danger of calculus anuria, but this immunity is far greater in patients nephrectomized for conditions other than calculus pyonephrosis and those in whom the remaining kidney is normal at the time of operation. The available reports concerning the condition of the remaining kidney are meager. The authors have encountered a few anuric cases in which a stone was known to be present in the remaining kidney at the time of nephrectomy, but there were several, including one of their own cases, in which the remaining kidney had been operated on previously for stone. From their study they conclude that anuria with acquired single kidney is less fatal if properly treated than other types of obstructive anuria. Calculous anuria seldom occurs after nephrectomy for conditions other than calculus pyonephrosis. It apparently is rare if the remaining kidney is normal at the time of the original operation. It is prone to occur in the nephrectomized cystinuric patient. In the majority of cases the indwelling catheter should be employed to overcome the anuria in preparation for removal of the obstructive stone or stones. Certain small ureteral calculi, especially if impacted in the lower ureter, may be removed by cystoscopic methods. The primary purpose of operation is to establish free urinary drainage. This may be accomplished by

operation on the kidney or ureter as circumstances dictate, but primary ureterolithotomy is especially indicated in the case of large ureteral stones. In serious cases and especially those in which operation has been previously performed, nephrotomy with or without removal of the obstructive stone or stones is the method of choice. In the majority of cases the obstructive stone or stones may be removed without the infliction of too much damage to the kidney.

Horseshoe Kidney—Sangree and his co-workers state that symmetrical horseshoe kidneys most commonly fuse by the lower pole, constituting the long kidney. They rarely fuse by the upper pole. Various degrees of dystopia and inclination to one side or the other may occur, represented by the 'caked' kidney, the 'sigmoid' and the L shaped kidney, these are classed as asymmetrical types. Fused kidneys are more commonly the seat of pathologic changes especially those incident to urinary stasis, than are normal kidneys. All surgical procedures on horseshoe kidneys should consider the possibility of anomalous vessels, often multiple in number and variable in position. The wedge shaped arrangement of calculi in a urographic examination should suggest the presence of a fused kidney. Concomitant congenital anomalies should always be investigated in a study of a case of horseshoe kidney. Horseshoe kidney disease should be considered in every patient with an abdominal mass and the triad of symptoms of umbilical or lumbar pain, gastro-intestinal disorders and urinary disturbances.

The Common Cold—Long, in discussing the common cold states that there is no specific remedy for the treatment of colds. His observations have led him to believe that the only rational treatment is to put the patient to bed at the onset of the infection and make him remain there for two or three days. Diet has little effect in the treatment of colds, but it is wise to force fluids moderately. A mild laxative is of value if constipation exists and it is a good plan to treat the distressing features of the disease symptomatically. If such a regimen is followed many infections will be aborted, many complications averted and many contact infections avoided. The multiplicity of the measures designed to prevent colds attests their lack of reliability. At present hardening exercises, vitamin feeding, ultraviolet radiation and bacterial vaccines occupy the first rank of popularity as prophylactic measures designed to protect one against colds. When, however, the relation of the hardness of persons is correlated with their resistance to infections of the upper respiratory tract it is found that the degree of hardness

or softness of an individual has nothing to do with susceptibility to colds (Gafafer). Carefully controlled observations on the use of vitamins A and D are disappointing, and in a recent report Clausen suggested that too much vitamin A may predispose a child to respiratory tract infection. The clinical studies of Colebrook and of Doull and his associates have demonstrated quite definitely that ultraviolet radiation does not reduce the incidence of infections of the upper respiratory tract nor does it decrease the duration or severity of such diseases. The failure of vitamin therapy as a prophylactic measure in colds can be understood if one bears in mind that in general the national dietary is not lacking in these essential substances. Early reports seemed to show that the incidence, severity and duration of infections of the upper respiratory tract were materially lessened in subjects inoculated with bacterial vaccines. During the last fifteen years, however, carefully controlled studies have demonstrated that there is but little basis for the claims of the enthusiastic exponents of bacterial vaccines. The failure of bacterial vaccines in the prophylaxis of colds can be explained on the basis that the ordinary bacteria of the rhinopharynx have nothing to do with the initiation of the primary infection of the upper respiratory tract known as the common cold. That these vaccines have little effect in reducing the severity or duration of the infection can be understood if it is remembered that in man there is little evidence of pathogenic activity by the so-called secondary invaders in uncomplicated common colds. At present the only prophylaxis against colds is the avoidance of contact with infected persons. There is no other method.

The Heterophile Agglutination Test in Diagnosis of Infectious Mononucleosis—Van Ravenswaay points out that two possible explanations have been suggested for the presence of sheep cell agglutinins in the serums of patients with infectious mononucleosis, the more obvious one being that the etiologic

agent of the disease, whether bacterial or virus in nature, serves as a heterogenic antigen in their production. As a precedent in such an assumption is the fact that the Shiga dysentery bacillus has been demonstrated to contain Forssman's antigen. An additional example of such a mechanism has been furnished recently by Buchbinder, who describes heterophile antibodies produced by organisms of the genus *Pasteurella*, which agglutinate avian erythrocytes. In contrast to this hypothesis, Meyer believes that the agglutinins normally present are merely increased in infectious mononucleosis. A similar type of increased serologic reaction has been noted in Berlin, where it has been found that frequently the serums of pregnant women agglutinate the Y dysentery bacillus in high titer. In attempting to determine whether other antibodies in the blood are increased in infectious mononucleosis, the author determined the diphtheria antitoxin content of the serums in four cases in which the heterophile agglutination test was strongly positive by intracutaneous titration in guinea-pigs. In none of them was the antitoxin content so high as is usually present in the serums of Schick negative persons. Until the cause of infectious mononucleosis and the details of its pathologic process are known, it is impossible to proceed further in explaining the reaction and the latter must be used as an empirical procedure. It is similar in this respect to the Wassermann reaction in syphilis and to the Weil-Felix reaction in typhus.

Diagnosis of Typhoid in Childhood—Webb observed seventy-five cases of typhoid in children in which the manifestations were quite different from the adult type. Sudden onset is the rule in young children; the most frequent early symptoms are fever, headache and abdominal pain. The disease usually follows one of these courses: (1) mild disease of short duration and variable symptoms, (2) a more severe attack with predominant nervous symptoms or (3) an occasional severe gastro-intestinal upset. A palpable spleen, a red tipped tongue and abdominal tenderness or distention were the predominant physical symptoms. Bradycardia and dicrotic pulse were seldom observed in younger children. Leukopenia is unusual in the child less than 5 years of age. An attitude of suspicion toward all fevers and an alert clinical study are necessary for the diagnosis of typhoid in the young child.

Simplified Treatment of Infantile Diarrhea—Cook points out that the reaction of stools in diarrhea gives the indication for the treatment and that the simple litmus paper test can be made easily not only by the physician but by the nurse or other attendant. It is an accepted procedure in urinary infections, but is not, she thinks, used sufficiently and appreciated in the diagnosis and treatment of intestinal infections, and too often patients with alkaline stools are put as a routine on a skimmed milk diet, sometimes with alarming and disastrous consequences. She has found a nonprotein diet effective in diarrhea of typhoid in which the stools are alkaline and in the diarrhea from improper food in which the stools are alkaline. In cases in which there are loose acid stools there is usually a ready response to an easily assimilated protein diet with plenty of fluids, after a preliminary cleansing of the intestinal tract with castor oil.

Dissociation of Thyroid from Sympathetic Nervous System and Reduction of Blood Supply to Thyroid in Angina Pectoris—Lyon and Horgan observed that the division and ligation of both superior and inferior thyroid arteries, when a subtotal thyroidectomy was performed, prevented the recurrence and persistence of hyperthyroidism and produced a beneficial effect on the hearts of the patients in a large series of cases. These observations led them to believe that the division and ligation of the thyroid arteries in cases of angina pectoris and congestive heart failure would produce correspondingly beneficial effects on the hearts of the patients and relieve them of symptoms. They performed the operation in two cases of angina pectoris, one with anginal failure and the other accompanied by aortic regurgitation and congestive failure. The operation relieved both patients of anginal attacks and the one of his congestive failure. It has enabled the patients to lead relatively active lives. The division of both superior and inferior thyroid arteries decreases the amount of blood entering the thyroid and cuts off all stimuli from the sympathetic nervous system to the gland. The effect of thus curtailing thyroid activity is to lower the metabolic rate, to decrease the circulatory demands and, therefore, to lessen the work of the heart.

The operation produces no change in the eyes (Horner's syndrome), lowers the basal metabolic rate, but does not produce myxedema, and will not, the authors believe, disturb calcium metabolism.

Gelatinous Carcinoma of the Breast—Lee and his associates point out that gelatinous carcinomas occur in many organs of the body which normally secrete mucus. A rare type is that occurring in the breast. Its incidence ranges between 1 and 2 per cent of all cancers of the breast. Gelatinous carcinoma of the breast occurs in two main forms (1) primary gelatinous carcinoma, in which the gelatinous features predominate, and (2) ordinary carcinoma of the breast with secondary gelatinous degeneration. The latter type may be divided into the myxoid or mucoid carcinoma, depending on whether the gelatinous changes arise by metaplasia in the connective tissue or by secretion directly from the carcinoma cells respectively. In the majority of cases the epithelial cells of the tumor are the source of the gelatinous material by a secretory process. Less frequently the connective tissue assumes myxoid characteristics by a degenerative process. Gelatinous carcinoma of the breast is usually slower in growth than the ordinary carcinoma. One of the reasons given for this fact is that the tumor arises on the basis of a preexisting benign mammary adenoma in many instances. No essential differences are observed in age, sex and race distribution and history of lactation and of trauma between the gelatinous and ordinary mammary carcinomas. The diagnosis of gelatinous carcinoma of the breast is made on the slow growth of the tumor, Halstead's sign, the usual signs and symptoms of ordinary breast carcinoma and the aspiration or punch biopsy. Metastases from it occur late in the course of the disease as compared with the usual type of mammary carcinoma, are usually confined to the axillary lymph nodes and do not necessarily show gelatinous changes. The end results of the authors' thirty cases indicate a considerably higher percentage of cures than in the usual types of carcinoma of the breast. The degree of malignancy is lower than in other carcinomas of the breast as evidenced by 57 per cent of five year cures as compared with 41 per cent in a control group.

Experimental Bone Regeneration.—Stewart in his experimental study, in an attempt to verify the observations of Murray

on bone degeneration, found that boiled bone grafts died and, when inserted into defects of the radius, there was no production of new bone about or within them. The only source of new bone formation was from the ends of the radius. Small fragmented live grafts used similarly were the sources of large amounts of new bone growth in each instance. Throughout the entire series of experiments, whenever a small bone chip was left behind at operation there was evidence of active bone growth from it. In all cases in which lime salts were implanted in the radial defects there was failure of regeneration of the shaft. The only effect of mixing traumatized muscle and lime salts in the radial defects was to create a few areas of calcification in necrotic tissue. No regeneration of the shaft took place. The only constant effect of implanting lime salts in carpal and tarsal defects was the production of a definite proliferative arthritis. No bone was laid down in the defects.

Treatment of Varicose Veins—Edwards gives the criteria used in any given case of varices at the Circulatory Clinic at the Boston City Hospital. At the patient's first visit the actual presence of varices and whether they occur in the distribution of the greater or lesser saphenous, the condition of the great saphenous vein and whether there is a positive Trendelenburg test, the condition of the valves of the perforating veins and the condition of the deep veins are determined. If the varices are limited to the distribution of the lesser saphenous vein, the injection treatment alone is used. The solutions employed are quinine ethyl carbamate for the small or medium sized varices, a 20 per cent solution of sodium chloride for the large varices, and a 5 per cent solution of sodium morrhuate for angiomas. If the varices are in the distribution of the great saphenous vein but the vein is not widened and the Trendelenburg test is negative, the injection treatment alone is used. If the Trendelenburg test is positive, the patient is hospitalized for ligation at the saphenofemoral junction, and the distal segment is injected with invert sugar and sodium chloride and then followed up in the outpatient department with injections as in the cases with negative Trendelenburg tests. If the Trendelenburg test is doubly positive, the saphenous is ligated, the incompetent perforation is excised and the remainder is injected in the outpatient department. These cases are relatively uncommon. In cases of obliteration of deep veins, it is a good rule not to disturb the superficial varices. The author has injected the varices in the lower leg in a case of occlusion of the inferior vena cava, with much improvement. In this case, however, the original deep phlebitis had not involved the deep veins of the leg proper. Patients with ulcer are treated according to the foregoing criteria, but injection is given cautiously far away from the ulcer until it is free from infection and, sometimes, the injection is not given until the inflammation is reduced by ligation alone or by supportive dressings. It has not been found necessary to excise an ulcer. If there is an incompetent perforator beneath the ulcer, the ulcer can be healed temporarily by ligation and injection. The perforator may then be excised several weeks after the ulcer is healed. Patients with phlebitis are treated as are patients with ulcer. The progress of the phlebitis is stopped by the ligation or small injections far from the phlebotic focus.

Interference in Schick Test by Diphtheria Antitoxin Injection—In an investigation as to how soon an injection of antidiaphtheric serum may be given in a suggestive case of diphtheria after the performance of a Schick test without invalidating the result of that test, Mayfield found that two hours is sufficient to get a reliable result to that test. It has been demonstrated that antidiaphtheric serum is much more efficient in inhibiting a positive Schick reaction when introduced by the intravenous route than by the intramuscular.

Barbituric Acid Paralysis—Landor and Salleh report a case of widespread paralysis following the use of a derivative of barbituric acid (evipan) for general anesthesia with no premedication. It was suggested that the case was one of acute beriberi, but the prolonged unconsciousness after the injection and the great loss of power in the trunk muscles were against such an explanation. The authors think that it was an undoubted case of late paralysis due to the administration of the anesthetic. Caution needs to be taken regarding dosage in patients already toxic.

*Diagnosis and Treatment of Doubtful Mammary Tumors M C Todd and E K Dawson—p 1041
Treatment of Postoperative Retention of Urine N R Barrett—p 1046

Diagnosis and Treatment of Mammary Tumors—Todd and Dawson group benign and doubtful mammary lesions that give rise to considerable difficulty in diagnosis into (1) benign tumors, (2) chronic infections, (3) cystic changes, (4) early carcinoma, (5) acute carcinoma, simulating infection, (6) pregnancy and lactation tumors and (7) fat necrosis. They discuss

the characteristics of each type and point out that, before deciding on the extent of treatment necessary in these benign and doubtful mammary tumors, the surgeon should consider various points in the history—age, duration of the growth, previous pregnancy and lactation, presence or absence of pain, discharge from the nipple, infection—and, in the examination, mobility or fixation, fluctuation, size, consistency and definition of the lump, retraction of the nipple and the condition of the axillary lymph nodes. None of these signs or symptoms are in themselves diagnostic, but a careful evaluation of each may provide a signpost that points to a benign or malignant growth. Age is an important factor, for no tumor of the breast in a woman more than 35 years of age can be regarded as certainly benign. The surgeon who decides to operate on a doubtful tumor has several roads open to him—local excision of the tumor, simple mastectomy and radical operation. The authors' analysis of a large series of doubtful tumors, with known later history, suggests that the two-stage operation is not dangerous but is undesirable. In women more than 35 years of age, simple mastectomy with immediate gross examination of the breast and submission of the tissue for microscopic examination is the method of choice for diagnosis. Should the tumor appear malignant to the naked eye the radical operation should be completed at once. Diagnostic mastectomy should be performed as the best initial stage of treatment in women of cancer age with a doubtful tumor of the breast, except in cases of acute (inflammatory) carcinoma and pregnancy and lactation tumors.

Treatment of Habit Vomiting in Infants—Pritchard states that the cure of habit vomiting differs with the cause but in all cases it consists essentially in the reeducation of a faultily acquired motor function and in the breaking of a pathologic or a conditioned reflex. In those cases in which the pyloric reflex is at fault, that is to say when a hypertonic sphincter refuses to relax in obedience to the inhibitory impulse of the vagus, the rational treatment is to remove the cause or causes that excite hypertonicity and combine this with the use of sedative drugs. The author usually commences treatment by giving one teaspoonful of some simple fluid and if that is retained he then gives two teaspoonfuls at the next feeding, and so on at intervals of two hours until the quantity reaches from 2 to 3 ounces (60 to 90 cc.) He then adds dry whey powder to the fluid, at first in small amount but always in increasing quantity, until it reaches three teaspoonfuls at each feeding. If up to this point the food has been well retained

he adds 10 drops (0.6 cc.) of cream at a time, gradually increasing the amount until 1 drachm (4 Gm) is used. Dry milk is next substituted for the foregoing mixture, beginning with 10 grains (0.65 Gm) and working up to the full amount indicated by the age and weight of the baby. By these means an operation may generally be avoided. In combination with this dietetic treatment the pyloric sphincter may be coerced into submission by the simultaneous administration of sedative or anodyne drugs. Undiluted condensed milk is suited to the requirements, for no matter how concentrated it may be it is digested easily and its caloric value is five times that of undiluted cow's milk, so that small quantities will supply the required number of calories.

Experimental Lead Poisoning in Pregnancy—Mitsui produced lead poisoning in ninety-four pregnant rabbits (most passed more than twenty days of pregnancy) and carried out the histologic and the histochemical tests by the method of Iwahashi on the fetuses, livers, kidneys and placentas. He compared the relation between the distribution and the histologic changes in the organic tissues to find what disturbance took place in the pregnancy as a result of the poisoning. As soon as lead was administered to the pregnant rabbits, intense anemia developed. The blood obtained by perforating the auricular vein presented a bright red watery appearance and decreased markedly in coagulability, gastric dysfunction, a decrease in body weight, often stillbirth and premature delivery were observed.

Filtration-Reabsorption Theory in Renal Pathogenesis—Govaerts believes that the filtration reabsorption concept clarifies many of the obscure points in renal physiopathology. He states that he has been able to confirm the work of Poulsson on the elimination of dextrose in phlorhizinized animals. The theory states that the glomerular tufts eliminate creatinine, urea and dextrose in the same concentration as in the blood, but that normally the dextrose is entirely reabsorbed. Under the influence of phlorhizin the reabsorption of dextrose is prevented so that, if this action is pushed to the limit, all the dextrose filtered at the glomerular level should be found in the urine. The elimination of creatinine allows the quantitative estimation of this filtrate. In considering the diabetic subject and the supposed variation of the threshold in the same person, he feels, as a result of observations on seven patients, that the excretion of dextrose varies in the same sense as that of the creatinine and has no relation to the elimination of water. Finally, in considering the various forms of Bright's disease, he concludes that the pure dropsical syndrome is based on a glandular lesion that renders the capillaries permeable to the proteins but does not affect the circulation. The changes in the tubules, which may be anatomically marked are nothing but the sign of a cellular degeneration. In the uremic and hypertensive syndromes the situation is different. The usual alteration in the uremic syndrome is an inflammatory process involving glomeruli and interstitial kidney tissue. He believes that these anatomopathologic and clinical differences are more easily explained on the basis of the filtration reabsorption concept of kidney function.

Experimental Surgery of Inferior Vena Cava G. Montemartini—p. 593
Treatment of Parathyroprival Tetany B. Paggi—p. 639

Influence of Suprarenals on Formation of Callus—Lucchese made observations on the evolution of experimental fractures in three groups of rabbits: (1) those previously subjected to either unilateral total or bilateral partial suprarenal-ectomy, (2) normal rabbits given subcutaneous injections of cortical extract and (3) normal rabbits, for control, that did not receive any treatment before or after the fracture was caused. Rabbits subjected to bilateral suprarenal-ectomy died. The osteogenesis was poor in the survivors of the first group, good in controls and excellent in the animals receiving the injections of cortical extract. The author says that the results of his experiments prove that suprarenal insufficiency retards the formation and favorable evolution of callus in comparison with the results observed in control animals, while the repeated injections of cortical extract provoke the accelerated evolution of an exuberant callus formation.

Alkali Reserve in Tuberculosis—Gutman made determinations of the alkali reserve in two groups of patients suffering from pulmonary tuberculosis: eighteen from chronic, stationary, incipient and unilateral forms, and thirty-four from grave acute tuberculosis in rapid evolution and in the pregonal stage. Some patients in this group had unilateral or bilateral artificial pneumothorax or pleurisy as a complication. The determinations were made by the method of Van Slyke with

the patients fasting and again after eating. The alkali reserve proved to be normal in patients of the first group and greatly diminished and tending to the development of acidosis in the second group. In these the organs concerned with the functions of neutralization of acids in the blood, especially the liver and the kidney, are in a decadent condition and the bulbar center, owing to chronic intoxication, is prevented from fulfilling its functions of elimination of the carbon dioxide and acids in the blood. Thus a vicious circle is established. The acid milieu of the blood prepares and favors the development of tuberculosis, which in turn provokes acidosis. Volumes of alkali reserve as low as 44, 42 and even 34 in one case, such as those observed by the author in patients having grave forms of tuberculosis, have not been previously reported, although all authors agree to the fact that the alkali reserve decreases as tuberculosis progresses and that the acidosis reaches its highest figures in preagonal stages of the disease.

Glycemia in Pulmonary Tuberculosis Without Diabetes—In a group of 752 patients having pulmonary tuberculosis in different stages of evolution Izzo and Sagastume performed 1200 determinations of the glycemia according to the method of Folin-Wu and of provoked hyperglycemia according to Escudero's technic (oral administration of 2 Gm of a 20 per cent solution of dextrose per kilogram of theoretical weight). The authors conclude that in patients with pulmonary tuberculosis glycemia during fasting oscillates within physiologic limits. There is neither true hypoglycemia, even in dying patients nor hyperglycemia. No case of glycosuria (Benedict and Fehling reagents) was observed during provoked hyperglycemia. The curves of provoked hyperglycemia in patients suffering from simple and moderate forms of pulmonary tuberculosis showed an almost identical aspect characterized by a terminal glycemia, three hours after the onset of the test, with figures near those given by the initial glycemia. The figures of maximal glycemia in these patients are the same as those observed in normal persons, and the return of glycemia to normal is somewhat retarded. In patients suffering from grave forms of pulmonary tuberculosis the return of glycemia to normal conditions after the test, is greatly retarded. Frequently the figures of terminal glycemia, three hours after the test are higher than those given by the initial glycemia. The absence of glycosuria and the behavior of the glyceimic curves during the test in patients suffering from moderate forms of pulmonary tuberculosis are explained as being caused by an insular hypofunction due to the hypo-alimentation of the patient, as well as to the general effects of the coexisting febrile and infectious conditions. The authors deny any specific influence of tuberculosis on the gluside metabolism.

Transplacental Heredity of Tuberculosis—Palacios Costa and Falsia report the results of their experiments with the inoculation of amniotic fluid or macerated placenta from tuberculous women to guinea pigs. They conclude that the transplacental infection by the tuberculous ultravirus is proved and that tuberculous infection of the amniotic fluid in cases in which the placenta is normal and, conversely, tuberculous infection of the placenta without contamination of the amniotic fluid are possible. Two patients, out of the group of three patients from whom the amniotic fluid was obtained, have corticopleural lesions and live in satisfactory conditions. The other patient in this group had fibrocaceous lesions and died twenty-three days after delivery of a living child. The woman who expelled the placenta used in the experiments had fibrocalcareous lesions. She lives also in satisfactory conditions. The four infants were separated from their mothers immediately placed under good care and fed by wetnurses and are in good general condition and developing satisfactorily.

Anomalies of Teeth in Congenital Syphilis—Guszman describes his observations on the teeth of 116 adults with congenital syphilis. He points out that there are a number of anomalies of the teeth the presence of which is considered suggestive of or characteristic for congenital syphilis. He mentions the following: (1) late second dentition, (2) microdontism, (3) absence of certain groups of teeth, particularly of the upper lateral incisors, (4) dystrophic crowns, that is, hypoplasia of the dental enamel with its numerous variations (apical and surface erosions, small circular or bowl-like erosions, "star" teeth or the so-called cloves teeth), (5) atrophy of the chewing surfaces, particularly of the first molars, (6) abnormal position of the teeth, (7) "amorphic" teeth (so-called fish teeth), and (8) Hutchinson's teeth. The author considers Hutchinson's teeth the most important of the dental anomalies of congenital syphilis but admits that they are not frequent. He observed them in 12 per cent of his patients with congenital syphilis. In spite of opinions to the contrary he asserts that really typical Hutchinson's teeth are found only in persons with congenital syphilis. Further he gives illustrations of fifteen different dental anomalies that he observed in his material: microdontism, absence of the two upper lateral incisors, large gaps between the teeth, hypoplasia of the upper median incisors, hypoplasia of the proximal portion of the crown of the upper median incisors, hypoplasia of the incisors and the canine teeth, crooked position of the teeth, misplacement of a tooth (so-called gum tooth), fish teeth, pointed teeth, typical Hutchinson's teeth, pivot tooth, teeth with half moon shaped erosions, wedge shaped cutouts on the upper median incisors and long amorphic teeth. The author admits that with exception of Hutchinson's teeth the anomalies are not a sufficient basis for a diagnosis of congenital syphilis, but they should be an inducement for further search for other symptoms, and in this manner they may lead to the discovery of the otherwise entirely latent congenital syphilis.

Epidermophytosis of Feet and Hands—Loos studied the mode of infection, treatment and prophylaxis of epidermophytosis. In order to clarify the widely accepted belief that the pathogenic agent of mycotic eczema is mostly transmitted in public baths, sport institutes and similar establishments the author inspected a number of baths and conducted a careful search for pathogenic fungi of the skin. He thinks that the negative results of these investigations do not entirely refute the belief, since in the cultures the disturbing growth of mold fungi could not be excluded. In studying the treatment he tested a number of antimycotics. He determined their growth inhibiting action by adding them to the culture mediums and their fungicidal action by letting them act on fungous material. He found that an entirely satisfactory substance, one that is effective in all cases, is still lacking. However, the tests permitted a comparative evaluation of the various substances that are now available. He found brilliant green the most effective substance, then follow in the order of their effectiveness: acriflavine hydrochloride, oxycyanate and solution of formaldehyde. Less effective are salicylic acid, benzoic acid and sulphur, and tar and alcohol have only a slight effect. Corrosive mercuric chloride, iodine and chlorine were especially fungicidal, while thymol inhibited the growth considerably. The metals were virtually ineffective. As most effective for the treatment he recommends brilliant green, benzoic acid and sulphur. The problem of prophylaxis is still unsolved. Nevertheless, it is possible to obtain certain successes. The author advises addition of chlorine to the bath water, cleaning the floors with phenol.

(carbolic acid) and disinfection of bath sponges and other bath accessories with solution of formaldehyde, thymol or alcohol. He thinks that acid foot baths, alcohol rubs and the use of disinfecting powders (sulphur) are to be recommended for personal prophylaxis.

Practical Application of Law for Prevention of Defective Offspring
O. Pedersen—p 1753

*Cephalic Index Kruse—p 1755

Acanthosis Nigricans in Gastric Carcinoma—Dambke points out that acanthosis nigricans has been considered a complication of carcinomatosis, although there have been cases in which a malignant neoplasm was not demonstrable. Since acanthosis nigricans is still an object of discussion and is a rather rare condition, the author feels justified in reporting the history of a man who had carcinoma of the stomach and who developed acanthosis nigricans. In the bend of the elbows, in the axillae, on the dorsal surfaces of the hands and feet, in the back and especially on the inner surface of the thighs there were pigmented areas, about the size of lentils, deep black, slightly raised above the surface, segmented, indented and almost wart-like. In contradistinction to the otherwise rough skin, these areas felt like velvet. The scrotum and penis were almost black. The localizations of the pigmented areas tallied with those described in other reports, but the histologic aspect corresponded only to a certain extent with those formerly described. The author thinks that the differences in the microscopic aspects are due to the fact that the cutaneous changes had existed only a few weeks when the patient died.

Cephalic Index—Kruse points out that Walcher, an obstetrician in Stuttgart, many years ago called attention to the fact that the shape of the head is largely determined by the fact whether the head of the young nursing is placed on a hard or a soft pillow. The author and his collaborator, M. Fischer, were able to corroborate this six years ago and Catel recently came to the same conclusion. He maintains that "environment" plays a much more important part in shaping the head than does heredity and concludes that the cephalic index is changeable and consequently cannot be considered a reliable indicator of race.

Heat Distribution in Ultrashort Wave Therapy—Gebbert describes experiments on the influence of wavelengths on the heat distribution in the body during ultrashort wave therapy. It is advisable to see that the distances between the electrodes are considerable, in order to produce a favorable percental depth action. The best medium between the electrodes and the body is air; however, for practical reasons other mediums may be interposed so that the effect of distance is attained. A good glass or a loose felt of sufficient thickness has been used. The thickness of the interposed medium is determined by the size of the electrodes. There were no sharply defined heat maximums in the various substances that served as test materials (bread, meat, leg of a hog), and on which different wavelengths were tried. To effect a uniform absorption of heat by the different mediums—skin, flesh, muscles, bones and marrow—it proved necessary to use rather short wavelengths (between 3 and 6 meters). The author advises that, before resorting to ultrashort wave

therapy of internal organs the relative heating of which is not known as yet, experiments should first be made on tissues that are stratified in a similar manner in order to determine the heating of the tissue in relation to the tissues in front and behind it. He suggests that these preliminary tests be made on a cadaver or on a phantom and thinks that this is the only way in which it can be determined how the ultrashort waves are best utilized.

Regeneration of Erythrocytes and Follicular Hormone—Since certain clinical observations indicate a connection between blood regeneration and the function of the gonads, Minouchi and Schwalm decided to investigate this problem experimentally in rabbits. The counting and the differentiation of the reticulocytes served as a criterion for the regeneration. It was found that even the spontaneous regeneration following venesection takes a different course in normal mature rabbits from that in rabbits castrated for some time. In normal animals regeneration is effected by flooding out of an increased number of all forms of reticulocytes, and more young reticulocytes begin to appear only if the bone marrow is taxed again and again, so that it becomes exhausted. In castrated animals venesection is followed at once by a considerable increase in the younger forms, while the total number of reticulocytes is not greatly increased. The administration of estrogenic substance alone, without other stimulation of the erythropoiesis, effects only slight changes in normal animals; an increase in the younger forms, which lasts only a short while, but in castrated animals an increase that persists slightly longer. The combination of venesection and administration of estrogenic substance, however, has effects that differ considerably from those which appear after venesection alone. In normal animals there appears, in addition to an increase in the total number, also a considerable increase in the young forms which may be interpreted as an intensive regeneration, a mobilization of all reserves. Castrated animals in which the function of the bone marrow is apparently impaired, react to this combined stimulation no differently than without the estrogenic substance. The authors conclude from this that estrogenic substance exerts a stimulating influence on the regeneration of the erythrocytes. To what extent these experimental studies can be applied to human subjects is yet to be determined.

Clinical Aspects of Ruptures of Uterus W. Maljowsky—p 167

Advisability of Renewed Conception After Eclampsia and Nephropathy—Seitz shows that observations so far have proved that renal lesions resulting from eclampsia and nephrosis as a rule disappear within several weeks. To preclude a too early severe taxing of the organ and thus its prolonged impairment, the author considers it advisable to prevent a new conception for from six months to one year. As long as there exists a rather severe hypertension, or if casts and protein are excreted in considerable quantities by a woman with eclampsia or nephrosis who formerly had normal blood pressure, the physician should advise against a new pregnancy. If conception should take place an expectant attitude should be taken. An interruption of the pregnancy is advisable only if it is found that a great exacerbation has set in and that threatening symptoms have appeared. The persistence of albuminuria, in which casts appear only in small numbers or are entirely absent in which the blood pressure is normal and in which the functional tests of the kidney reveal fairly normal conditions, is no reason to advise against a new pregnancy. If, following a pregnancy nephrosis, there should actually develop a chronic nephritis or a contracted kidney, it is reasonable to take steps to prevent a new pregnancy. If under these conditions conception has taken place and severe disturbances in the compensation have set in, the pregnancy should be interrupted. The author points out that there are cases in which the most exact functional tests

no longer disclose an impairment of the kidney and in which a renewed pregnancy again leads to nephrosis and eclampsia. All methods known so far do not permit a definite evaluation of such cases during the period when the woman is not pregnant, and consequently nothing remains but to take a chance with a new pregnancy.

Birth Injuries of the Nose—Birke observed nine cases of birth injury of the nose among 542 newly born infants. A connection with the process of birth was considered definitely established only in cases in which noticeable lesions of the skin existed over the injured area. In four of the nine cases the delivery had been complicated (forceps, twins, frontal presentation), and in the other five cases there existed first or second occipital positions together with a considerable disproportion between the fetal head and the birth channel. The nose injury was not treated in any of the cases. The author points out that fractures of the nasal bones heal more quickly than any other fractures. He calls attention to the fact that asymmetries of the nose of newly born infants are almost the rule (519 out of 542) but that a connection with the process of birth can be proved in but few cases.

Estimation of Genital Disorders by Sedimentation Speed of Erythrocytes—Guthmann and Neuhaus determined the reliability of the sedimentation speed in the evaluation of inflammatory genital disturbances on the basis of 1,892 tests that were made in 1,138 cases. They determined the occurrence of certain values (10, 20, 30 cm and so on after one hour) in various inflammatory disorders of the genitalia and found that the conformity between the severity of the disorder and the value of the sedimentation speed is most pronounced if the process is either severe or light. In processes of average severity there are considerable fluctuations, and the reliability is therefore correspondingly reduced. The authors compared the reliability of the sedimentation reaction and of the leukocyte count and found that the latter is more reliable in new processes, whereas the former is of greater importance in the estimation of subacute and chronic processes. In cases in which the inflammatory processes of the genitalia concurred with syphilis, it was found that the existence of syphilis does not noticeably diminish the reliability of the sedimentation reaction.

What Is Best Method of Manual Artificial Respiration and in What Manner Is It Best Accomplished? C J Mynlieff—p 1758

*Dangers of Chemical Contraceptives K E Fecht—p 1764

Differentiation Between Syphilis and Tuberculosis—Berendes calls attention to the similarity between the external manifestations and the histologic aspects of syphilis of the upper air passages and those of tuberculosis. Moreover, it has been observed that in cases of lupus of the skin or of the mucous membranes the Wassermann reaction is occasionally positive, in spite of the fact that syphilis is absent. The positive outcome of this reaction is thus not always a reliable indicator of the real nature of the disorder. On the other hand, it has been known that syphilis and tuberculosis existed together. However, it is much more frequent that in the upper air passages there occur disturbances in which syphilis is masked by tuberculosis. The microscopic examination of the lesions may reveal changes of a tuberculous character but if they are in reality of a syphilitic nature much valuable time may be lost, for the lesions of tertiary syphilis may lead to ugly disfigurements in the face and to dangerous cicatrizations in the larynx and esophagus which can be prevented if antisiphilitic treatment is begun early enough. The author describes four cases the histologic aspects of which suggested tuberculosis, but, since the serologic tests gave positive syphilis reactions, antisiphilitic treatment was instituted and judging from the results obtained with this treatment it must be concluded that the lesions were syphilitic rather than tuberculous. The author knows of no definite reason why the differentiation of syphilis and tuberculosis is difficult especially when the upper air passages are

concerned, but he assumes that the strongly lymphatic character of the lining membrane may be responsible.

Dangers of Chemical Contraceptives—Numerous observations indicating the danger involved induced Fecht to call attention to chemical contraceptives, which are supposed to paralyze the motility of the spermatozoa. If the chemicals are rather concentrated, there is danger that they will injure the mucous membrane of the vagina and the uterus, particularly if used for long periods. Severe leukorrhea may develop, or erosions of the cervix and of the vagina. Chronic inflammation of the endometrium may spread to the uterine tubes, which may become obstructed and thus cause sterility. Since 1925 the author has observed 150 cases of primary and 200 cases of secondary sterility that could be traced to the use of chemical contraceptives. In addition to this he treated 275 cases of chronic endometritis and approximately 200 cases of inflammation of the tubes traceable to the continuous use of chemical contraceptives. Moreover, since chronic irritation may favor the development of carcinoma, he considers it possible that the chronic inflammations and erosions produced by contraceptives on the cervix and in the vagina may eventually lead to carcinoma, and he observed a number of cases of cancer in which this etiology seemed probable. The greatest danger of chemical contraceptives lies in the possibility that the spermatozoa may be damaged, although still remaining able to fertilize the ovum, and eventually lead to the development of defective offspring. He observed two cases, one with physical defects and another with both mental and physical defects, in which a causal connection with the effects of contraceptives was almost certain, while in three others there were indications that they were contributory factors in the development of defective offspring.

Nutrition of Tuberculous Patients W Neumann—p 1390

Animals as Carriers of Paratyphoid Bacilli—David points out that there are different types of paratyphoid bacilli with distinct morphologic, biochemical, serologic and pathogenic characteristics and that the type determines to a large extent the symptoms of the disorder. Thus paratyphoid, the symptoms of which resemble typhoid, is generally caused by types A and B Schottmüller, whereas Breslau, Gärtner, Newport or similar strains of bacilli are usually detected in the gastro-intestinal forms. In animals paratyphoid is caused either by types the pathogenicity of which for human subjects has not been proved as yet or by strains that cause the acute form in human subjects and are designated as the enteritis types (Breslau, Gärtner, Newport and others). After calling attention to the fact that these bacilli may not only cause disorders in the intestine of these animals but also invade the internal organs and the muscles the author points out that the ingestion of meat from animals that have had an enteritis infection may cause meat poisoning in human subjects. Animals may become carriers of enteritis bacilli without showing symptoms of disease, and foods may become contaminated with their excretions or their meat may not be recognized as a possible source of disease. Moreover, cows that are carriers may produce contaminated milk and milk products may likewise become infected. The author calls attention to the increasing incidence of food poisoning caused by meat from infected poultry and by eggs. Reports about eggs as sources of infections with Gärtner and Breslau bacilli have come from England, France and, particularly, Germany. Breslau and Gärtner infections have been traced also to rats and mice as carriers. In discussing the measures for the prevention of paratyphoid-enteritis infections the author stresses the necessity of eliminating animal carriers, and he recommends periodic examinations of live stock in order to detect them.

Heart Action in Pregnancy and Following Delivery

—Anthony and Hansen point out that respiration and circulation are taxed more severely during pregnancy but that the disturbances in the heart action cannot be estimated properly unless the behavior of the normal heart during pregnancy is understood. They studied the beat volume and the minute volume in a number of women before and after delivery, employing the physical method of Broemser and Ranke. They found that tests on different days revealed differences that may be observed also in healthy subjects. The beat volume is hardly ever changed by the delivery. A reduction of the systole during pregnancy is noticeable in but few cases. The diastole and the pulsation are always shorter at the end of pregnancy. Since the pulse frequency is greater during pregnancy than after delivery, the minute volume is likewise greater.

Pulse Wave Velocity in Pregnancy and After Delivery

—Anthony and Hansen determined the pulse rate before and after delivery with the method of Broemser and Ranke in the aorta, in the brachioradial artery and in the femoral artery. A tabular report shows the results of these tests, listing the systolic blood pressure, and the pulse rate in the three examined vessels before and after delivery. During pregnancy and the puerperium the pulse rates of the brachioradial artery and the femoral artery are about the same. This indicates that the elasticity of the vessels of the extremities is not noticeably changed during pregnancy, and there is no reason to assume that the tonus of the vascular muscles is changed during pregnancy. In the aorta, the velocity of the pulse wave is slightly reduced during pregnancy. The authors think that this may be due to the pressure of the enlarged uterus.

Enterococci During the Puerperium—Hauptstein points out that, morphologically considered the enterococcus is an oval, lancet-shaped diplococcus. He describes his studies on the significance of the enterococcus in puerperal women. He comes to the conclusion that the enterococcus is normally present in the lochia without endangering the puerperal woman. As regards its pathogenicity, it apparently takes a position intermediate between the virulent streptococci and the avirulent organisms, perhaps similar to that of the colon bacillus. Thus the uterus may harbor the enterococcus and yet puerperal fever need not develop. However under certain conditions (long duration of delivery, stasis of the lochia and retention of the fetal membranes) enterococci may cause febrile disorders and if the enterococci have found in the uterus conditions that favor their growth and if the natural protective devices of the organism fail, the development of a hysterogenic enterococcal general infection is possible.

- Aspects of Günther's Congenital Porphyrin A H Müller—p 460

Specific Dynamic Action of Foods in Obesity—Sylla says that by determining the basal metabolism two forms of obesity may be differentiated, one with a subnormal metabolic rate and one with a normal or supernormal rate. The obesity with lowered basal metabolism is considered of thyrogenic

origin, while the form in which the metabolism is normal or supernormal is considered hypophyseal in origin. In most of the patients with thyrogenic obesity the action of the foods is not greatly impaired, but hypophyseal obesity is characterized by a reduction in the action of the food. Deviations from this rule must be considered polyglandular disturbances. The hypophyseal action on the metabolism probably takes place largely by way of the thyroid. The active principle is contained in the "thyrotropic" hormone. The author demonstrates in five cases how the reduced food action may be normalized by means of the thyrotropic hormone. The body weight of these patients decreases and thus this treatment gives prospects of a causal therapy of endocrine obesity.

Cutaneous Manifestations in Caisson Disease—Mellinghoff observed on the extremities and to a lesser degree on the trunk of a patient with severe caisson disease a clear marmorization of the skin. When the patient coughed or was subjected to Valsalva's experiment, the marmorization became more noticeable. It disappeared gradually, but at first it had a tendency to recur while the patient was coughing. The author attempts an explanation of these cutaneous manifestations and in the conclusion he points out that only in the severest cases, in which the skin is dark blue and swollen, does the cutaneous stasis play an important part in the course of caisson disease. In this event considerable quantities of blood may be stored in the skin so that there is, so to speak, a bleeding under the skin, a process that may exacerbate the circulatory collapse of patients with severe caisson disease. The cutaneous symptom is significant also, because fine marmorization may develop quite early at a time when all other signs of caisson disease are still absent. The patient likewise had noticed these signs but had paid no further attention to them. In looking for this sign, one may recognize persons who are likely to develop caisson disease. Such patients should avoid work that leads to caisson disease or they should receive special medical attention.

Aspects of Günther's Congenital Porphyrin—Müller reports the history of a man now aged 63, who from early youth had suffered from skin eruptions in the form of blisters that existed for from eight to ten days and then disappeared again. At first the eruption appeared on the hands, but later also on the face. The eruption did not cause itching, but the rupture of the blisters was accompanied by a burning pain. The blisters used to be the size of a bean but in recent years they reached the size of a silver dollar (38 mm). After the blisters rupture they dry up and a white tissue forms at their base. This remains for several months, is shed and sores form which discharge a yellowish white fluid. These heal slowly but leave deep tissue defects and brownish spots. The skin appears tightly drawn over the bones and in some portions it is hard. The auricles have been partly destroyed and the neck shows scars and depigmentation, as do also the hands. The patient noticed that the blisters developed with greater frequency during the spring and summer. He had a hypersusceptibility of the skin to exposure to the sun and to rays from artificial light sources, but he never protected himself against sun rays. For years he had excreted large amounts of porphyrin. In the urine the uroporphyrin and the coproporphyrin were increased and in the blood even more so. At times the porphyrin concentration of the blood surpassed that of the urine. The feces likewise contained excessive amounts of coproporphyrin. Moreover, coproporphyrin and uroporphyrin were found in the gastric juice and in the hepatic bile, and the porphyrin was increased in the gallbladder. The sputum was free from porphyrin. Examination of the nervous system revealed no abnormalities, and the digestive tract was free from changes traceable to the primary disease. However, the calcium and iron metabolisms were highly abnormal. The changes in the calcium metabolism became manifest primarily in the bone structure. Whereas roentgenoscopy disclosed a considerable increase in thickness and density on the cranial bones other portions of the skeletal system proved deficient in calcium. To prove that there is a connection between porphyria and the calcium metabolism the author calls attention to the experimental porphyrin deposits in growing bones and in callus and to efforts to cure rickets by porphyrin. The patient also had a hypochromic anemia with a decrease in the

resistance of the erythrocytes, an eosinophilia and disturbances of the renal function. On the basis of these observations the author concludes that it cannot be doubted that this is a case of congenital porphyria. He attempts a uniform explanation of all disturbances that are accompanied by a disturbance in the porphyrin elimination. Among other things he points out that the clinical aspects of porphyrin diseases make the relations between porphyrin and calcium or a disturbance in the calcium metabolism, the probable cause of disturbances in the neuroregulation of the sympathetic functions.

Method of Obtaining Secretion from Puerperal Uterus
 Buhlitschenko and Dertschinsky think that the detection of bacteria in the uterus of healthy women can perhaps be explained by mistakes in the withdrawal of specimens from the uterus. They maintain that neither Döderlein's cannula nor Walther's rod precludes the transfer of an infection from the cervix into the uterus, and for this reason they devised a new technic. The lochia are withdrawn from the uterine cavity by means of a syringe to which a Braun catheter has been attached. The opening of the latter has been made wider for this purpose. The syringe is covered with a sterilized condom. Following disinfection of the external genitalia the vagina is opened by spoonlike specula. The cervix is cleansed with sterile cotton, and Braun's catheter together with the covering condom is introduced into the cervical canal up to the internal os. A wire mandrin perforates the condom so that owing to its elasticity it glides downward. At the same time Braun's catheter is pushed into the uterine cavity, the syringe is operated and a specimen of the uterine content is obtained. The authors are convinced that this technic makes impossible a transfer of the contents of the cervix into the uterus and they conclude that in the greatest majority of puerperal women, in whom the temperature did not increase, the uterine contents were sterile.

Formation of Vagina by Means of Skin Grafts—
 Matwejew, after calling attention to the disadvantages of artificial vaginas formed from the small or large intestine, describes an operation that he employed successfully in eight patients in whom vagina and uterus were completely absent. In the last operation of this type, which he performed in 1932, he modified his original method slightly in that the flaps were removed from the thigh in such a manner that the lower freshened edge of the lateral flaps, at the site of their connection with the matrix, was not at the lower freshened edge of the upper flap but 0.75 cm higher. If this is done the upper flap is cut from the skin and the mucous membrane of the vaginal introitus and of the perineum in the form of a rectangle, 4 cm in width and from 6 to 7 cm in length, so that its upper edge is 3 mm. below the urethral opening. This flap is lifted and underneath it, partly with a knife and partly by blunt methods, a canal, from 10 to 11 cm in length and 5 cm in width, is formed between the rectum and the urethra. Following this two flaps, from 10 to 12 cm in length and 5 cm in width, are cut from the inner surface of the thighs almost parallel to the labia majora. A thin layer of fat is removed with the flaps. At the lower edge the flaps remain connected with the skin of the thigh. The flaps are sutured together in such a manner that they form a tube, this is placed in the preformed canal and is sutured into position. Then a loose gauze tampon is introduced into the newly formed vagina and is left there for four or five days. Care must be taken that the tampon is neither too tight nor too loose, for in the first instance necrosis might result and in the second event displacement is likely. He suggests that instead of the gauze tampon a sponge cylinder may eventually be used. He asserts that the immediate as well as the late results of his method are favorable.

Cataphoretic Serum Reaction in Syphilis—Delbaere describes a serologic reaction for syphilis based on the lowered electrical charge carried by antigen particles suspended in a syphilitic serum. The amount of this decrease of charge is measured by means of the cataphoretic displacement rate of these particles, which is compared to that of a lipid dye, simultaneously suspended in the serum. By means of the results obtained with this reaction in 1,147 serums, which were at the same time submitted to the Wassermann reaction and two of the usual flocculation reactions, it proved that this reaction is more sensitive than the extremely sensitive Müller reaction. The author, therefore, does not doubt its specificity.

- *Traumatic Fat Embolism E. H. Hansen—p. 1201
 Urticaria Factitia K. H. Baagø—p. 1211

Traumatic Fat Embolism—Of the eight cases of respiratory and cerebral forms of fat embolism reported, the first presented clinically and anatomopathologically a characteristic picture of the cerebral form and is described in detail by Hansen. A free interval of about eighteen hours followed fracture of the femur, humerus, radius and patella in an automobile accident. The patient then became unconscious during sleep, there were involuntary urination and accelerated pulse and somewhat later rise of temperature and bloody, coffee ground vomit. Death occurred about fifty-eight hours after the accident. Microscopically fat emboli were seen in the lesser and the greater circulation. The author says that in the respiratory form of fat embolism diagnosis is sometimes impossible and in other cases difficult, especially when the picture resembles that of wound shock. A free interval and rise of temperature should suggest fat embolism. In bronchopneumonias after trauma, fat embolism should be considered. The symptoms of the cerebral form of fat embolism should be borne in mind in puzzling and unexpected general cases after fractures and other traumas. In fatal cases following traumas, especially fractures, fat embolism should be looked for, particularly in the absence of lesions which in themselves satisfactorily explain the outcome. Prophylaxis seems to be of doubtful value and no treatment has given convincing results. Attempts to avoid the entrance of more fat into the blood stream are regarded as rational. A case is cited to illustrate probable spontaneous recovery after fat embolism.

- *Intestinal Invagination in Childhood L. Ø. Christensen—p. 1229

Intestinal Invagination in Childhood—Of fifty-four cases reported in fifty-two children, thirty-four in boys and eighteen in girls, thirty occurred in children less than 1 year of age, the oldest child was 12. The mortality was 16.6 per cent. In Christensen's opinion bloodless treatment is indicated in fresh cases, particularly in the first year of life, when the general condition is greatly affected. If observation in the following hours shows reposition to have failed, there is a possibility that improvement in the general condition will afford a better outlook for operative intervention. The normal operative method used was laparotomy through incision of the right side of the rectus. The author says that while the importance of rapid operation has frequently been emphasized, the greatest care in treatment of the intestine is a factor no less important. Resection in small children should be a last refuge, and recovery is seen after conservative treatment of apparently grave cases. Evagination of the intestine should be avoided as far as possible. Reposition can often be done intraperitoneally. The lines of treatment for invagination are not yet fixed, but the tendency is in the direction of surgical treatment as the normal method.

PERORAL GASTROSCOPY

INCLUDING EXAMINATION OF THE SUPRADIAPHRAG-
MATIC STOMACH

CHEVALIER JACKSON M D

AND

CHEVALIER L JACKSON, M D
PHILADELPHIA

Endoscopic examination may be said to be indicated for the diagnosis of every disease of the stomach, though not necessarily in every case of such disease. It does not replace nor lessen the necessity for any other method of diagnosis nor does it replace other methods for treatment except for the removal of foreign bodies.¹

There has been fully realized the prophecy made seventeen years ago by one of the early workers in this field, who said "Gastroscopy is not simply a feat. It has a field of usefulness that will increase as our skill, and knowledge increase."²

Broadly speaking, there are three methods of gastroscopy: one by using an open tube, another by using a lens system and a third by combining both the open tube and the lens system. Each of these methods has its uses and its limitations.

METHODS OF GASTROSCOPY

Open-Tube Gastroscopy—This is the method required for the removal of foreign bodies and the taking of specimens of tissue for histologic examination. It has all the advantages of looking directly at tissues examined rather than at a lens-projected or prism-deflected image.³ Its limitations are: (a) It requires a straight and rigid instrument, (b) much training and skill in the introduction of the instrument are necessary for the safety of the patient and (c) the explorable area is limited even with the aid of the very important external abdominal manipulation.⁴ It is perfectly safe so far as the stomach is concerned, but serious and even fatal trauma of the esophagus may occur if its passage is attempted by the untrained. These dangers are eliminated by skill and an especial element of safety arises from the fact that the esophageal lumen ahead is always followed. The tube is never

advanced until a lumen is found.⁵ A lumen ahead cannot be seen with a lens system.

Lens System Gastroscopy—The advantage of a lens system is that a much larger field of vision is available. The limitation is the danger of introduction of an instrument presenting no esophageal lumen ahead. This danger is obviated by the introduction of an open tube through which a lens system is passed. The development by Wolf and Schindler of a flexible distal half for the lens-system gastroscope has eliminated much of the difficulty and danger of blind passage, provided there is no disease of the esophagus.

Danger—Almost all the danger in gastroscopy is associated with the insertion through the esophagus, especially at the cricopharyngeal and diaphragmatic pinchcocks. Even the flexible gastroscope, if put into the mouth and ruthlessly pushed, is more likely to enter the mediastinum or pleural cavity than the esophagus.⁶

Complications—Pneumothorax, mediastinal emphysema, mediastinal abscess, gaseous cervical cellulitis and subcutaneous emphysema are all possible complications of ill advised or unskilled instrumentation. None of these need follow careful, gentle insinuation of a gastroscopic tube by the technic of finding the lumen.⁷

Technic has been already minutely described⁸ and hence need not be given here. The watchword of safety is "find the lumen." In finding it anatomic knowledge is useful and even essential but it must never be taken for granted that the lumen is where it ought to be, the lumen must be found wherever it may be. With the open-tube gastroscope it is found by sight, with the semiflexible gastroscope it is found by sense of touch. If it cannot be found by touch, it may be strictured or compressed or deflected. Skilful open-tube gastroscopists will always examine the esophagus with the open tube first, not only to determine the presence or absence of adequate lumen unweakened by disease but to exclude esophageal disease as a cause of the patient's symptoms. Roentgen study will help, but its negative results are not always conclusive, in some cases a radiographically and fluoroscopically adequate lumen will not permit the blind passage of the flexible gastroscope because the lumen is not as large as it looks to be in the roentgenogram, or because there are webs, shelves or offsets in the axis that are not revealed by the roentgen examination.

NORMAL GASTROSCOPIC APPEARANCES

The appearances of anything are made up of color, form and movement

Color—This is in the eye of the observer and hence subject to a personal equation. Individual variations within the normal are almost as great as in the pharynx. It may be pale and anemic or red and engorged. Another variable is the degree of illumination. A brilliantly overilluminated electric lamp will blanch the apparent color, a weakly illuminated lamp will deepen the color and render it more reddish in tint. Therefore it is essential that the degree of illumination be always the same. Still another variation may come from the presence of even a small amount of food, this deepens the color.² Under proper illumination the color of the gastric mucosa is a deep pink as seen in the open-tube gastroscope, a pale orange red as seen in the lens-system rigid gastroscope, and a somewhat deeper red as seen in the flexible gastroscope. In going down with the open-tube gastroscope the esophageal mucosa is noted as a pale rather bluish pink, the transition to the deeper yellowish pink on passing through the hiatal pinchcock into the stomach is readily noted (for gastroscopic purposes the abdominal esophagus does not exist). When a lens system is put in through the open tube, even with a much greater illumination, the color is usually some-

Figure 1

Figure 2

Fig. 1—Bleeding round ulcer of the gastric mucosa in a woman aged 28. The blood trickled from the erosion on the fold and formed a little pool in the lower posterior part of the stomach (patient recumbent). Open tube gastroscope. Usually the bed of the ulcer is yellowish but if bleeding, as in this case, the bed of the ulcer is crimson with blood. The surrounding mucosa is usually not as inflammatory in appearance as one would expect. There are in some cases subepithelial hemorrhages in spots.

Fig. 2—Carcinoma involving the lesser curvature in a man aged 33 as seen through the flexible lens system gastroscope. The window of the gastroscope is directed toward the pylorus. The extensive infiltration seen at the right of the field was a pale lavender mottled with white and violet. Both color and form of image of malignant tumors vary widely.

what deeper and more orange in tint. This is in great contrast to the color of the esophagus by the open tube and especially to the pale pink color normally seen through the lens-system cystoscope. Branching vessels are visible with the open-tube gastroscope.

Form—The form of the structures seen through the gastroscope varies greatly with the region, the movements and the degree of inflation, if used. Folds crowd in on the mouth of the open tube. They are not ordinarily seen on the proximal part of the lesser curvature, but increase in prominence beyond, they are not conspicuous on the anterior wall. In other regions the folds crowd in until driven back by a few strokes of the handball. With a window plug and increased pressure they may be made to disappear almost completely from any part. It is difficult to see the pylorus because of the mounding forward of the posterior gastric wall caused by the spine. With the flexible gastroscope and moderate inflation, folds are not usually noticeable on the anterior wall, on the lesser curvature they are visible toward the antrum. In other regions of the

stomach, folds are conspicuous unless flattened by inflation, in some regions they can be obliterated by inflation pressure. After passing a distance of a few centimeters from the cardia, one gets the impression of a trend of the direction of the folds toward the pylorus. There are folds, however, that seem to run in any direction. Branching of folds is noted. The forms of the pylorus and the antrum vary with movement and position but may be identified by general average form. The left end of the antrum may be contracted so as to lead an inexperienced observer to believe that he is looking at the pylorus. All anatomic forms seen through the open tube are actual size, through a rigid lens system they are magnified, with a flexible lens system they are diminished.

Movement—The stomach is in constant movement, yet this is not troublesomely in evidence at gastroscopy except as it causes a great variation in the images seen and recorded. Under the influence of movement the images give the impression of prominence, recession and even disappearance of folds. The most constant form of fold, as noted many years ago,² is one of horseshoe shape seen at the right as the stomach is entered with the open tube. At times a puckering of the folds may give the impression of numerous narrow folds at the pylorus (fig. 3).

NEGATIVE OBSERVATIONS

Though negative observations are of less value than positive ones, they are of more importance today than they were in the earlier days of the work.⁹ It is possible for a small isolated lesion to be overlooked, but, if the observer's eye is educated to gastroscopic vision, normal mucosa can be recognized and gastritis or other diffused lesions can be excluded. With the flexible gastroscope the larger explorable area renders a negative opinion still more valuable, but it must be remembered that no image is received from the distal end. It comes through a side window. To give importance to negative observations this side window must be turned to face successively in all possible directions. This is done by rotation, and a full free swing around the theoretical 360 degrees is not always practically attainable because of the mounding forward of the posterior gastric wall by the spine. Careful search and repeated examinations with the flexible gastroscope will yield valuable data even in a negative way.

Contraindications—When clearly indicated in a patient free from cardiovascular disease, there are no absolute contraindications to open-tube gastroscopy except lack of skill in performing it. If obstructive disease of the esophagus prevents entering the tube all the way to the stomach no harm is done and the esophageal malady is positively diagnosed. The same may be said of the combined open tube and lens-system gastroscope in which the open tube is first passed by sight. For lens-system gastroscopes, rigid or flexible, disease of the esophagus is a contraindication because of the special danger of a blindly passed instrument in such cases.

INDICATIONS FOR GASTROSCOPY IN DISEASE

Every patient with gastric symptoms should have a gastroscopic examination for diagnosis, unless there

⁹ Jackson (footnotes 27). Jackson, Chevalier. Esophagoscopes and Gastroscopy. Laryngoscope 21:923 (Sept.) 1911. Gastroscopy. New York M. Rec. 71:549 (April 6) 1907. Recent Progress in Endoscopy of the Larynx, Trachea, Bronchi, Esophagus and Stomach. Proc. Internat. M. Cong. London 1913, sec. 15. Laryngoscope 23:721 (July) 1913.

are overbalancing contraindications. Today this seems a radical statement, but the examinations with the gastroscope in so many cases have made such important additions to the pathologic data that one cannot but feel that a full study of a case of suspected gastric disease has not been made if gastroscopy has been omitted. It should be repeated for emphasis, however, that gastroscopy is not indicated in any case as a substitute for other methods of examination, therefore, no other method should be omitted. Gastroscopy reveals the pathologic changes, it gives little informa-

Figure 3

Figure 4

Fig 3—The pyloric antrum showing the open pylorus beyond the overhanging fold. The form of the antrum varies widely in form and movement so that no one image can be regarded as characteristic but the pylorus itself when normal varies little and is always easily presented and identified.

Fig 4—Gastroscopic view showing chronic gastritis in the herniated stomach in a man aged 54. The surface is mottled and superficial erosions are visible on the three folds toward the left. The color was bright orange red.

tion, except inferential, as to function. Persistence of symptoms after gastro-enterostomy calls urgently for gastroscopic examination not only of the stomach in general but of the anastomotic orifice especially. Localized gastritis and erosions are often found in such cases.

Hematemesis is a strong indication for gastroscopy whether the vomited or regurgitated blood is bright red or brownish.¹⁰ In all such cases the open-tube gastroscope or at least the standard esophagoscope should be passed first to exclude disease of the esophagus. If this is negative, the flexible gastroscope may be passed for more complete exploration of the stomach. A bleeding point may be seen corresponding to a slight erosion, but care is necessary to avoid mistaking for the source of hematemesis the slight bleeding sometimes noted from tubal contact, this comes from minute, bulging capillaries, is only a few drops in amount, and does not reappear when wiped away. The wiping test can be applied only if the open tube is used. In some cases a bleeding point and fresh blood can be found, and a lake of it may be seen in the dependent part of the stomach (fig 1). Older brownish blood may be present, but it may not always be possible to recognize the dark interplical streaks of fluid through the flexible gastroscope, and because of the angle of vision a lake may not be presented to view. In such cases these evidences of bleeding may be obtained with the open tube, and after aspiration the source may be found. If not, the examination should be repeated at a number of subsequent seances with the flexible gastroscope.

Chronic gastritis is very commonly associated with a moderate amount of bleeding. Larger hemorrhages are, of course, usually found in ulcer, cancer and breaking down gumma. In these conditions biopsy with the open-tube gastroscope is indicated. The following

abstract of a case is illustrative of the value of gastroscopy in locating the source of hemorrhage.

CASE 1—Hematemesis from erosion of the gastric mucosa. A neurotic, anemic, emaciated woman, aged 28, with a fearful dread of cancer, brought up considerable quantities of blood, spattering it about over the bed or walls or furniture as it was projected from the mouth during almost daily attacks of choking, coughing and strangling. The department of diseases of the chest had referred the patient with a negative report to the gastro-enterologic clinic. All examinations, including gall-bladder, gastric analysis and roentgen-ray, had been negative except that the examinations of the vomited blood indicated that it had been in the stomach, though it was never of "coffee ground" character. Gastrotaxis was considered a possibility. The patient was referred to us to determine the source of blood, first by esophagogastroscope, and if that was negative we were to do a tracheobronchoscope also. The esophagus was found free of lesions, but longitudinal streaks of blood were noted. Passing downward in the stomach, three separate bleeding points were noted. With each of them the blood reappeared promptly when wiped away, in the moment before reappearance it was noted that the first and third points were erosions and that the intermediate one was a small ulcer. The latter is sketched in figure 1. The hematemesis ceased after treatment by a dietary regimen and the administration of bismuth subnitrate dry on the tongue.

Neurotic Patients with Gastric Symptoms.—A tentative diagnosis of hysterical gastric neurosis is a clear indication for gastroscopy. Over and over again in such cases a lesion, most often a chronic gastritis, has been found, and appropriate treatment has yielded good results. In many instances of supposed hysterical gastric symptoms we have found the stomach normal, but the symptoms fully accounted for by a chronic esophagitis, a peptic ulcer of the esophagus or other entirely unsuspected esophageal lesions. Treatment directed to the gullet caused the supposed gastric symptoms to disappear. The following abstracts from our records are examples.

CASE 2—Peptic ulcer of the esophagus mistaken for hysteria. A woman, aged 23, had had various unquestionably hysterical manifestations since she was 15 years of age. For two years she complained of fulness, pressure, weight epigastric pain and distress after eating, at times to get relief she would induce

Figure 5

Figure 6

Fig 5—Chronic edematous nodular gastritis of the supradiaphragmatic stomach as seen through the open tube gastroscope in a woman aged 47.

Fig 6—Edematous hypertrophic gastritis with polypoid formations as seen through the open tube gastroscope in a woman aged 37. Biopsy demonstrated that the tumor like masses were not truly neoplastic they were made up of hypertrophic, edematous gastric mucosa.

vomiting by putting her finger in her throat. Burning pains would persist for half an hour or less, after this she would be comfortable until she ate again. Medicines and special food formulas produced no discomfort. "Hunger pains" were often noted. Functional, roentgen and all other studies were essentially negative. A tentative diagnosis of hysteria was made and the patient referred to us for gastroscopy. The stomach by direct inspection was normal, but there was a small peptic ulcer in the lower third of the esophagus surrounded by the usual extensive area of peptic esophagitis.

CASE 3—Chronic gastritis treated for hysteria A girl, aged 16 years, had had a number of hysterical attacks accompanied by complaints of a lump in the throat, vague pains in various regions and severe "blinding" headache that disappeared after it was too late to go to school. Recently, during summer vacation, she had paroxysms of colicky pain, eructation, and a feeling of pressure vaguely referred to "the pit of the stomach." The patient had been treated as hysterical. All functional tests and laboratory examinations including roentgen studies were negative. Gastroscopy revealed an intensely red mucosa, swollen folds that obliterated valleys between them, small erosions and rather large patches of tightly adherent secretions. Treatment by the gastro-enterologist caused a disappearance of these objective evidences of chronic gastritis, and general medical care and management cured all the psychic manifestations.

INDICATIONS FOR GASTROSCOPY FOR FOREIGN BODY

Any foreign body that has reached the stomach spontaneously by natural passages may be brought back

Fig 7—Toy watch in stomach of a child aged 4 years illustrating the indications for gastroscopic removal. The toy watch had been in the stomach for more than a month. Gastroscopic removal through the mouth was indicated partly because of doubt as to passage out of the stomach but chiefly because of the probability that the length of the foreign body would cause it to jam in the turns of the duodenum even if it did pass through the pylorus. No anesthetic general or local was necessary.

up by the same route. The indications for doing so, however, may or may not be present. Briefly, they are as follows: (1) a foreign body too large or a pylorus too small¹¹ to permit passage of the intruder through the pylorus, (2) a foreign body of character rendering its passage through the intestine dangerous, this danger may arise from sharp points or edges (fig 7),^{11b} size (figs 7 and 8),¹² or toxic qualities, as radium capsules.¹³ Pins and needles may penetrate the pyloric ring. There

are many borderline cases, as for instance open safety pins. Many have been known to pass through the intestine harmlessly, but some have lodged and perforated. A large safety-pin, if not too large to pass the pylorus, may lodge in the turns of the duodenum.^{11b} If it passes these it will go through ring-end first and the spreading point will prevent the keeper hooking anywhere, on the other hand, a very small pin may turn over and try to pass onward, point and keeper leading, this is almost certain to cause lodgment. Peroral pyloroscopy has been found necessary for removal of an open safety-pin hooked in and propping open the pylorus.¹⁴ These contingencies render it advisable to remove open safety-pins by peroral gastroscopy. Foreign bodies impacted in the supradiaphragmatic stomach require removal by peroral gastroscopy.^{11b} Before a gastroscopy for foreign body is done in the subdiaphragmatic stomach, a lateral roentgenogram is required to make sure that the foreign body really is in the stomach and not in the colon anteriorly or the duodenum posteriorly nor in the costophrenic sulcus of the left lung.¹ A foreign body may rap many times at the pyloric door before it is permitted to pass the threshold. A month is long enough to wait for any foreign body to pass out of the stomach. Gastroscopic removal is too simple and safe a procedure to justify waiting longer. During the waiting period no cathartics should be given and no change in diet should be made, normal intestinal contents and normal peristalsis afford the best conditions for safe passage. The subject of gastroscopy for foreign bodies is elsewhere discussed more fully.¹⁵

Gastritis—It is in uncomplicated gastritis that the generally invaluable diagnostic aid of the roentgen ray is least helpful. It is therefore in this disease that gastroscopy has one of the largest fields of usefulness in supplementing the diagnostic work of the gastro-enterologist. A tentative diagnosis of gastritis calls for diagnostic gastroscopy, and the call is very urgent when treatment based on the inferential working diagnosis has not resulted in a satisfactory degree of improvement. In many of our cases gastritis was associated with preventriculosis (so-called cardiospasm). In most of these, so far as determined by objective demonstration, the gastritis was limited to the left two thirds of the stomach, complete exploration of the stomach was not made. All study and treatment were concentrated on the preventriculosis to which the gastritis was assumed to be secondary. It seems justifiable to infer that the constant trickling of acid fermented foods from a preventriculous esophagus caused the gastritis. In most cases the gastritis improved as the esophageal stasis was eliminated.

The following is an abstract of the history of a typical case of gastritis mistaken for cancer.

CASE 4—Chronic gastritis with symptoms suggesting cancer A man, aged 62, had been under treatment during nearly two years on a diagnosis of cancer based on pain, anemia, emaciation, color of the skin, absence of hydrochloric acid, and a small palpable mass. Gastroscopy revealed an old chronic gastritis with scarring and a tiny spot of recent ulceration.

The gastroscopic appearances of chronic gastritis vary greatly, especially as seen through lens-systems. The

gastroscopic appearances in the open tube are easily recognized by any one familiar with the appearances of mucosal inflammation. They look very much like similar processes on other mucosal surfaces. The same cannot be said of the lens-system and flexible gastroscopes. It is necessary for the observer to acquire familiarity with the modifications imposed by the lens-system, especially the darkening and reddening effect, as elsewhere herein mentioned. In some cases of gastritis the mucosa is a still deeper red, in other cases it is pale, anemic almost cicatricial, and one gets, sometimes, the impression of a deep violet tinge. The

Fig 8—Bobette pin in the stomach of a child aged 2 years removed through the mouth by gastroscopy. Removal was indicated because of the length of the pin in relation to the age of the child. It was determined that the pin was too long to make the turns in the duodenum, involving great risk of transfixion. Cases of gastroscopic removal and of duodenal transfixion of bobette pins of this kind and size in children of this age have been elsewhere reported by us (footnotes 1 and 11 b). The lateral roentgenogram was necessary to determine positively that the foreign body was in the stomach.

presence of a little food deepens the color. Through a lens system the swollen folds or rugae give the impression of crowding together, obliterating the open spaces between ridges. There is blurring of the sharp outlines. In parts of the stomach where there are no ridges the mucosa is mottled, dark and velvety in appearance. Purulent or mucopurulent secretions, when due to gastritis, are tightly adherent. Swallowed discharges from the throat and nose are usually not adherent to the walls of the stomach.

The appearances of gastritis vary to a much greater extent than pathologic studies based on postmortem gross and histologic examinations would lead one to believe. It would seem that a reclassification of the varieties of gastritis based on gastroscopic observations will be necessary. Localized as distinct from diffused gastritis is much more commonly seen gastroscopically than one would suppose from autopsic records.

It must be remembered that the presence of inflammation does not exclude malignant or benign ulcer or other lesion, because once the epithelial barrier is passed in any disease the mixed secondary infections produce inflammatory conditions.

Gastroscopy of the Supradiaphragmatic Stomach—Hiatal hernia of the stomach is a rather common condition in our records. Most of these patients came with a tentative diagnosis of esophageal disease, in many instances cancer of the esophagus. In all these cases a definite diagnosis was reached by gastroscopic examination.

The open tube is best for this purpose because the cavity of the supradiaphragmatic stomach is not suffi-

ciently large or distensible to get away from the walls a sufficient distance to obtain a good image in a lens-system instrument. Moreover, the folded walls collapsing over the distal end of the open tube gives an ideal opportunity for minute inspection. After the folds have thus passed minute inspection before the mouth of the tube, a handball is attached in place of the aspirating rubber tube and the folds are gently pushed back. To prevent the escape of air, the proximal mouth of the tube is covered with the thumb. When the thumb is removed from time to time the cavity of the herniated stomach is demonstrated, and the folds are seen slowly to regain their collapsed positions more or less influenced by the negative intrathoracic pressure created by inspiration. Our gastroscopic observations indicate that the esophagus in some of these cases is not congenitally short but fails to grow in length. We believe that the vertical growth of the esophagus depends on the downward drag of the diaphragm and abdominal viscera. When the hiatus is congenitally large, this drag on the growing esophagus is lacking. The primal factor is therefore not a congenitally short esophagus but a congenitally large hiatus esophageus. Our observations in other cases indicate that the hernia was acquired in adult life during violent continued vomiting.

Gastritis of the Supradiaphragmatic Stomach—

Chronic inflammation of the mucosa is commonly present in the herniated part of the stomach. Erosions often accompany the inflammation, the usual site of erosion is at the entrance of the herniated stomach, in other words the part that properly belongs in the grasp of the hiatal pinchcock of the diaphragm (figs 9, 10 and 11). These erosions and the form of gastritis limited to the supradiaphragmatic stomach often give rise to symptoms suggestive of ulcer of the subdiaphragmatic stomach in cases in which the latter is normal. This form of gastritis limited to the herniated stomach does not seem to have been recognized (figs 4

Figure 9

Figure 10

Figure 11

Fig 9—Superficial erosive evanescent type of ulcer with inflammatory zone on the mucosa at the esophagogastric junction in a patient with hiatal hernia of the stomach. The stenosis, the ulcers and the inflammatory zone are typical of hiatal hernia and are probably due to contact of regurgitated acid gastric juice with this esophageal mucosa.

Fig 10—Appearance in same patient as in figure 9 three weeks later. The ulcers have healed but the stricture remains. It is oval.

Fig 11—Appearance in same patient as in figures 9 and 10 a month later. A new crop of ulcers has developed and they are in new locations.

and 5). The following is an abstract of an unusual case.

CASE 5—Chronic aphthous or herpetic gastritis of the supradiaphragmatic stomach. A woman, aged 50, complained of intermittent attacks of burning and pain in the epigastrium extending through to the back, sometimes coming on immediately at other times within a few hours, after eating. Eructations were noted occasionally. The symptoms would all disappear for a few weeks at a time and seemed more severe for a few days when they recurred. The recurrent attacks

were regularly periodic, though menstruation had ceased. The patient was referred for gastroscopy, with negative reports from the gastro-enterologic and gynecologic departments. Passage of the open tube revealed the hiatal part of the esophagus somewhat narrowed and located at a much higher level than normal. On three of the folds there were superficial yellow erosions. Each time these erosions were touched with the lip of the mouth of the tube the patient flinched. The tube (8 mm) met with slight resistance but passed on downward entering a supradiaphragmatic stomach with chronically inflamed mucosa. The hiatal passage was narrower than usual in cases of herniated stomach. At a subsequent examination, other erosions were noted. Those first seen healed. A 7 mm tube was later slowly and carefully insinuated into the subdiaphragmatic stomach. This was found to be apparently normal. Dilatations of the narrowing at the hiatal pinchcock produced permanent relief. There had been no recurrence of symptoms when the patient was last heard from three years later.

New Growths in the Stomach—Benign and malignant growths are usually evident at roentgen examination, yet we have often been called on to decide definitely, by means of gastroscopy, before the patient would consent to operation. This was most often in patients who objected to an exploratory operation. In quite a number of our cases a small malignant ulcerative growth was found with the gastroscope after roentgen examination was negative. In other cases gastroscopy has been of the utmost value in relieving the anxiety of the physician and the anguish of the patient by demonstrating the benign character of a condition supposed to be malignant. The following notes are abstracted from the histories of examples of such cases.

CASE 6—Chronic gastric ulcer In a man aged 40 a previous diagnosis of cancer had led to a miserable year of anxiety accentuated by the fact that the father and a sister had died of cancer. The symptoms were loss of weight, epigastric distress unrelated to food, vomiting occasionally showing "coffee grounds," anorexia, constipation, occult blood and anemia. Repeated gastric analyses demonstrated absence of free hydrochloric acid. The report of a roentgen examination was negative. Gastroscopy revealed chronic esophagitis, chronic gastritis and a chronic ulcer at the edge of the antrum in the segment merging into the lesser curvature. The appearances were so typical of chronic ulcer that we did not deem it necessary to take a specimen, but yielding to the request of the medical and surgical consultants, we did so nipping out the margin of the ulcer. Dr. V. L. Andrews found no evidence of malignancy. The relief of the patient's anxiety and an ulcer regimen resulted in a complete cure. A year later, when the patient came in none of us recognized him, he weighed nearly 200 pounds (90 Kg.).

CASE 7—Adenocarcinoma of the stomach In a man aged 24, typical general symptoms of carcinoma were present but doubt was cast on this diagnosis because of the negative roentgen examination, the age of the patient, hyperchlorhydria, the intermittence and the duration of the symptoms (six years), and the absence of a palpable mass. Gastroscopy revealed a chronic gastritis and a soft bleeding mulberry-like lesion on the posterior wall close to the antrum. A specimen taken from this was reported by Dr. V. L. Andrews as adenocarcinoma. At operation J. Hartley Anderson found no metastases and a favorable limitation in the extent of the growth. Partial gastrectomy gave three years of freedom from local recurrence. The patient died of sigmoidal fibrosarcoma.

Biopsy—The taking of a specimen of tissue through the open-tube gastroscope is easily done, and hundreds of cases without a single complication have demonstrated its freedom from danger when done with proper precautions. The nipping off of a benign growth or the removal of fungations from a malignant one involves no risk. In the ulcerative type a specimen

may be taken from the edge of the ulcer. There might be risk in biting deeply into the bed of the ulcer, especially if it should prove to be benign. In the infiltrative type of lesion not yet ulcerative and especially when the mucosa is not grossly abnormal, it is best to postpone the taking of a specimen until the ulcerative stage has been reached.

CONCLUSIONS

1. Contraindications to gastroscopy are few, they are of two kinds, general and local. General contraindications are (a) very high and irreducible hypertension and (b) a moribund or hopelessly ill condition of the patient.

2. Local contraindications to the passage of an open tube do not exist except in a case of aneurysm encroaching on the esophagus. Any disease of the esophagus constitutes a contraindication to the use of the flexible gastroscope.

3. Lens-system gastroscopes present no image or structure in advance of the distal end, therefore preliminary open-tube examination is advisable for safety.

4. The only dangers in flexible-tube gastroscopy are incidental to passage through the esophagus. The dangers are entirely eliminated by careful work and by preliminary exclusion of esophageal disease.

5. A diagnosis of gastric neurosis or of hysteria with gastric manifestations should not be made until both esophagoscopy and gastroscopy have excluded organic disease of the esophagus and stomach.

6. Gastric symptoms so often arise from esophageal lesions that open-tube esophagoscopy is indicated, and for reasons given it should precede gastroscopy.

7. For diagnostic inspection of the stomach the flexible gastroscope is best. It does not permit of biopsy nor of removal of foreign bodies, however. For these, the open tube is required.

8. Gastroscopy for a foreign body is a safe procedure that is advisable when the size, shape and other qualities of the foreign body renders its passage uncertain or unsafe.

235 South Fifteenth Street

ABSTRACT OF DISCUSSION

DR. GABRIEL TUCKER, Philadelphia: I should like to speak of open tube gastroscopy. The authors have given the only safe rule: "Find the lumen." I should like to repeat the injunction and add "Find the lumen and follow it." The great danger in gastroscopy is from complications that follow trauma during the introduction of the gastroscope. If the lumen is found and followed, there should be no complications in a patient whose esophagus has been found normal on examination with the open tube. The authors have mentioned elsewhere the necessity for careful roentgen study of the cervical thoracic and lumbar spines to demonstrate any abnormality that might contraindicate gastroscopy. This cannot be too strongly emphasized. Free mobility of the spine is necessary in gastroscopy and careful check-up should be made in order to prevent injury to the spine as well as to avoid injury to the esophagus. Careful roentgen study of the spine, esophagus and stomach should be made in every case prior to gastroscopy. In esophagoscopy the open tube must enter the stomach if the examination of the esophagus is complete. The area of stomach explored is limited to the cardiac end. It is often found however that the lesion producing the esophageal symptoms is in the cardiac end of the stomach, particularly carcinoma. I have been able to visualize peptic ulcer of the cardia. Biopsy may be done if indicated. In gastroscopy for foreign body it is very important to know that the foreign body is in the stomach immediately before attempt at removal.

I have used a method of localization which I have not found recorded, which will demonstrate the location and also its relation to the hiatal esophagus through which the gastroscope must enter for removal. The localization is accomplished by fluoroscopy and films in the anterior-posterior and lateral planes with the patient in the position required for gastroscopy. A rubber tube is passed, from 14 to 16 size, a feeding tube of the Levin type may be used, a sufficient length of tube is passed to place a coil in the stomach or until contact has been made with the foreign body. Films and fluoroscope will demonstrate the foreign body if it is in the stomach and also show its relation to the hiatal esophagus. The tube can then be withdrawn and gastroscopy done immediately and there will remain no opaque material to obscure fluoroscopic guidance. The stomach may be emptied of secretions before the tube is withdrawn, if desired. The greater number of cases of foreign body occur in children. Gastroscopy is most difficult in children, because the pressure of the tube compresses the trachea and may obstruct breathing to a dangerous degree. Tracheal pressure has been avoided by improvements in the gastroscope making the size of the tube smaller without lessening the working lumen of the tube. Thus has been accomplished by the perfection of a one-piece lamp light carrier which I devised, for the infant bronchoscope, with the assistance of the George P. Pilling Company of Philadelphia. This light carrier lamp has been adapted to a slender esophagoscopic tube. Two sizes of tubes have been constructed for infants 35 mm by 35 cm for older children, 5 mm by 35 cm. The larger gastroscopic tube will permit the use of curved forceps that go around the corner," which one frequently finds necessary for the removal of foreign bodies. The use of the lens system gastroscope in its present stage of development should prove a valuable aid in the diagnosis of gastric lesions. It will not be of aid, however, in removal of foreign bodies or the treatment of diseases of the stomach until further improvements are made.

DR WILLIAM A. SWALM, Philadelphia. It has been my privilege to work up many of these cases clinically and then to visualize the stomach by means of the Wolf-Schindler, semi-flexible gastroscope. This gastroscope is about the size of the old-fashioned large stomach tube. The upper half is more rigid than the lower half, and the lower half has a series of lenses, the lower lens being just far enough from the tip so that it is not easily bathed by the stomach juices. The authors have performed considerable preliminary studies on dogs and have correlated the position and partial flexibility of the gastroscope in association with the x-ray department. They state that the method does not replace or lessen the necessity for any other diagnostic or therapeutic method, except for the removal of foreign bodies. There are very few contraindications to its use except for such local conditions of the esophagus as varix, stricture, carcinoma, ulcer, and the so-called cardiospasm. Other contraindications are hypertension, hopelessly ill patients, and aneurysm. Cancer and ulcerations of the stomach, gastritis and other conditions were observed without undue discomfort to the patients and without any mishaps. In acute pain of suspected ulcer, the procedure should be postponed. Success or failure in diagnosis depends to a great extent on the proper preparation by one experienced in the technical procedures of gastric analysis and lavage, and the correlation of these observations with the trained endoscopist of the esophagus and stomach. After careful observation of the fasting gastric residuum and lavage extractions the stomach tube is allowed to remain in situ for drainage until sufficient time has elapsed for morphine and atropine to exert their physiologic effect. The latter point is important for two reasons: first to quiet an apprehensive attitude on the part of the patient and second to check excessive secretion. The patient should be fully informed and assured that a surgical operation is not contemplated. Visualization through the gastroscope is somewhat analogous to that of the sigmoidoscope except that in the lens system, as mentioned by the authors, the mucosa of the normal appears somewhat of a deeper orange red shade and that the view is at right angles or slightly retrograde from the lens to the extent of 60 degrees. Sufficient distance from the walls of the stomach is necessary in the lens system, and this can be readily facilitated by adequate air injection by an assistant, using a hand bulb.

DR SAMUEL WEISS, New York. Gastroscopic examination has been practiced on the continent of Europe for more than half a century, and in this country a number of men, notably Drs. Chevalier Jackson and Max Einhorn, have devised methods and instruments for inspection of the stomach under direct vision. In 1930 I presented before this section a new gastroscope for visualization and photography, the important features of which were a flexible outer tube, a focusing prism and a movable reflecting mirror. I should like to call attention to certain clinical aspects of gastroscopy. To make the procedure useful, one must aim to make it less drastic by eliminating such measures as the use of morphine and atropine and hospitalization. An important feature of gastroscopy concerns the preparation of the patient. The stomach must be empty. In the new gastroscope the outer flexible tube has a large catheter through which lavage may be effected without undue strain on the patient. After this catheter is withdrawn, the optic is introduced. If there is recurrence of secretion, the optic may be withdrawn the catheter reintroduced and suction again applied. Thus one secures a clean field without removal of the outer tube. Regarding the choice of a drug to replace morphine and atropine, I use perparin hydrochloride, a micro-crystalline yellow powder almost tasteless slightly soluble in water and alcohol but readily soluble in chloroform and ether. Perparin is an isochinolin benzyl derivative closely related to papaverin but three times as active and much less toxic. The antispasmodic effect appears within ten to fifteen minutes after injection, which can be done in the office or clinic with the patient ambulatory. In addition, the outer tube of the gastroscope is smeared with a 1 per cent nupercaine ointment, which will anesthetize the esophagus so that morphine or other opiates are unnecessary.

DR EDWARD B. BENEDICT, Boston. During the past year at the Massachusetts General Hospital we have conducted gastroscopic examination in about 110 cases using the new Wolf-Schindler flexible gastroscope. The flexibility of the instrument makes it an entirely safe procedure, we have had no difficulty whatever with any case during or after gastroscopy. Gastroscopy is carried out under local anesthesia. We have even done a number in the outpatient department and allowed the patients to go home shortly afterward. The most important use of the gastroscope is probably in the diagnosis of gastritis. We have established that diagnosis in some sixty cases with or without association with peptic ulcer. In bleeding cases which are unexplained and undiagnosed by the x-rays we have been able to demonstrate small actively bleeding erosions in the mucosa. In some cases diagnosed as gastric neurosis in the past the gastroscope has been taken without any sign of neurosis and a definite diagnosis of gastritis has been established. In carcinoma and ulcer the gastroscope is of great use in confirming the roentgen diagnosis, in localizing the lesion, and in defining its characteristics and extent.

Test for Protective Power Against Yellow Fever—A method of testing sera for protective power against yellow fever is described and designated as the intraperitoneal protection test in mice. The test consists essentially of the inoculation of mice intraperitoneally with yellow fever virus, fixed for mice, together with the serum to be tested and the simultaneous injection of starch solution into the brain to localize the virus. If the serum lacks protective power the mice die of yellow fever encephalitis. The test is highly sensitive. Consequently it is useful in epidemiological studies to determine whether individuals have ever had yellow fever and in tests to find whether vaccinated persons or animals have in reality been immunized. When mice were given large intraperitoneal injections of yellow fever virus fixed for mice, the virus could be recovered from the blood for four days although encephalitis did not occur. If the brain was mildly injured at the time of the intraperitoneal injection the symptoms of yellow fever encephalitis appeared six days later, but the virus was then absent from the blood. Strains of white mice vary greatly in their susceptibility to yellow fever—Sawyer, W. A., and Lloyd, Wray. *The Use of Mice in Tests of Immunity Against Yellow Fever*, *J. Exper. Med.* 54: 533 (Oct.) 1931.

FEMORAL HERNIA

OPERATIVE REPAIR BY LIVING FASCIAL SUTURES

ROBERT LEE PAYNE, MD

NORFOLK, VA

My purpose in this paper is to show that absorbable sutures of catgut in the repair of any type of hernia do not give the permanent results afforded by unabsorbable sutures. It is not my object to go into details covering the history, the diagnosis or the generally accepted methods of surgically treating femoral hernia. The only point to bring out is the technic of the adaptation of living fascia to the closure of femoral hernia. I presume that fascial suture has already been used by many surgeons in the repair of femoral hernia, but I can find no illustrated technic in the literature to cover the use of living fascial sutures and therefore present certain minor details which have proved in my hands more satisfactory than any method hitherto employed.

The fundamental principle is that the autogenous fascial suture is a living tissue, which is never absorbed and under aseptic conditions never dies. I¹ recently published the results obtained by the use of living fascial suture in 200 cases of inguinal hernia, and the progressive satisfaction in this group stimulated me to apply the same procedure to the closure of the patulous femoral canal.

To the exceptionally well prepared and experienced surgeon the drawings in this paper will appear very

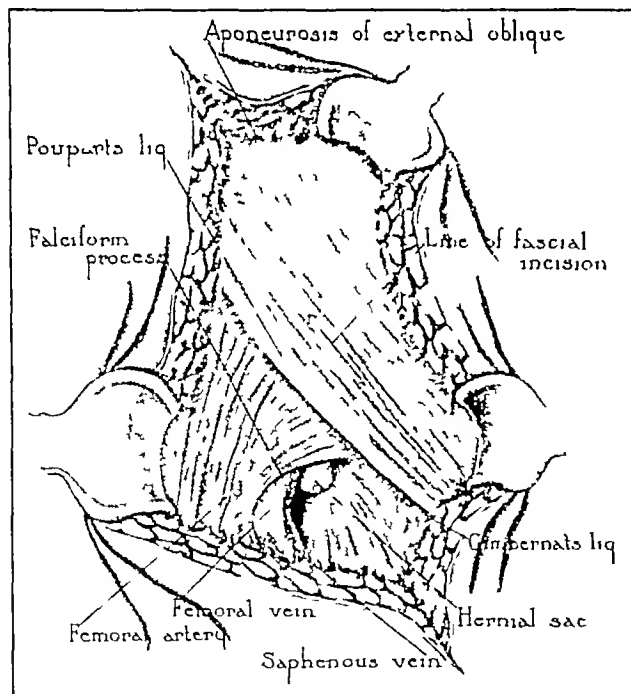

Fig 1—Anatomy and line of incision in the external oblique muscle from which the fascial suture is taken. The inner leaf is cut free at the upper end and left attached to the pubic bone at the lower end.

simple and primer-like in their details. There is no pretense of anything new or original. To the younger surgeons and to operators of limited experience the execution of the technic may prove difficult and hazard-

ous. This will be directly proportionate to their intimate familiarity with the anatomy of the region. The operator must be absolutely certain of his knowledge and familiar with the anatomic structures adjacent to and forming the femoral canal. In every operation for femoral hernia one must identify the femoral

Fig 2—Dealing with femoral ring by the femoral approach below Poupart's ligament. The fascial suture is passed under the outer leaf of the external oblique through Poupart's ligament and through Gimbernat's ligament. The pectineal fascia on the inner side of the ring is approximated to the falciiform process on the superior and external side of the ring.

vessels, the epigastric vessels, the obturator artery (often in an anomalous position) and, most important of all, the ligamentum pubis or Cooper's ligament.

While the drawings illustrate a method of operative closure by the femoral or subinguinal approach, this route is far from ideal. I have had successful results from closure of the lower end of the femoral canal by fascial suture as illustrated, but I believe that the inguinal approach above Poupart's ligament is by far the most correct anatomically and will more surely give permanent results in a large series of cases. This is a simple problem of physics. Given pressure within a tube or canal, it is obviously easier to prevent escape by closing up the inlet than the outlet. Furthermore all femoral hernias are acquired and can recur unless the abdominal entrance to the canal is closed.

It is a pity that there exists such a fallacious and rather common impression as that femoral hernia is a simple operation, that anatomic dissection is not essential to success, and that simple ligation of the sac without closure of the ring will result in a permanent cure. In the first place, it is practically impossible to ligate the sac sufficiently high when approached from the subinguinal route and, regretfully, I know that a femoral hernia can recur both after high ligation of the sac and after ligation with attempted closure of the ring below Poupart's ligament.

It is also to be deplored that the rank and file of operating surgeons in this country are not familiar with

the method of approach and repair of femoral hernia by the route above Poupart's ligament. One desiring information should consult the admirable paper of Seelig,² Watson's³ book on hernia and the recent book on surgical anatomy by Callander.⁴ In the last few years I have asked almost every surgeon I have met what method he used in operating for femoral hernia. The answer has been almost invariably the femoral approach below Poupart's ligament, and the impression prevails that the problem is so simple that any hospital intern is capable of securing a successful result.

The utilization of human controls for comparison of operative technic presents a delicate and awkward problem. In my early experience with fascial sutures, however, I had a case in a woman with bilateral femoral hernia. The right side presented a large opening with a large sac containing omentum. The left side had a

Fig 3—The ring closed by fascial suture. The free end of the fascial suture is then slit and one end of it passed under the last stitch and a square knot tied. The free ends are then turned upward as shown in the inset and additional anchorage of these is obtained by two ties of silk or chromic catgut.

small ring with a small sac containing a loop of bowel easily reduced. On the right hernia I performed a fascial closure of the ring by the crural or subinguinal route, as illustrated in this paper. On the left side, since the opening in the canal and the sac appeared so small, I decided to make a short textbook type of incision below Poupart's ligament and used the textbook method of closing the ring with number two chromic catgut sutures, according to the Halstead technic. The operation of the right hernia resulted in a permanent cure, but to my chagrin the hernia on the left side recurred in six months.

To McArthur⁵ belongs the credit of first demonstrating the use of fascial implant or suture taken from the inner leaf of the external oblique aponeurosis. To

Gallie⁶ surgery is indebted for broadening the field of application of fascia in closing all types of hernial defects. Moschcowitz⁷ in 1907 presented the inguinal approach as a new operation for femoral hernia, though to Ruggi⁸ should belong the credit of first describing the method in 1893. Subsequent descriptions of the

Fig 4—The superior or inguinal route of approach for the cure of femoral hernia. The fascial suture has been taken from the inner leaf of the external oblique muscle and is shown free in the drawings. The incision is carried down through the transversalis fascia to the peritoneum.

Fig 5—The sac has been pulled back and amputated and the neck has been closed. Cooper's ligament is then dissected out.

operative technic by the inguinal route for the cure of femoral hernia have followed closely the method described by Moschcowitz. The results of American

surgeons show a recurrence ranging from 8 to 30 per cent, the French and German surgeons place recurrence at from 8 to 36 per cent in femoral hernia operated on by the femoral or subinguinal route. My own experience, by the femoral route, is in keeping with that of other surgeons. With these dismaying figures one can see how Moschcowitz with his large experience in hernia would seek to develop and present the inguinal

Fig. 6—The fascial suture has been passed behind the cord or round ligament through Gimbernat's ligament thence under the transversalis and Poupart's ligament underneath the outer leaf of the external oblique. The suture then doubles back and is passed under Cooper's ligament once or twice thus obliterating the abdominal opening of the femoral canal by approximation of Cooper's ligament to Poupart's.

method of operation, which has proved so satisfactory. The suggestion herein described of fascial suture would seem to offer an additional safeguard.

With regard to femoral hernia the outstanding contribution of Seelig in 1914 on the inguinal approach was most timely, especially because of his accurate description of the ligamentum pubis or Cooper's ligament. There is no feature in the inguinal operation for femoral hernia that is as important as the dissection and utilization of Cooper's ligament in the closure of the abdominal opening to the femoral canal.

The inguinal approach for the cure of femoral hernia is the ideal route, for it affords the most feasible avenue for handling strangulation or resection when this is a complication. If constriction in the neck of the sac prevents reduction of its contents, the division of Gimbernat's ligament, on the inner side of the ring, is the safest solution, as there are no important structures encountered and this does not interfere with the subsequent closure of the defect.

In using fascial strips for suture it is absolutely necessary that the suture be firmly anchored at both ends. The method here illustrated provides that the natural attachment to the pubic bone be preserved while the free end is fixed by a square knot, and additional anchorage is secured by silk or chromic catgut. Provided firm anchorage of the free end of the fascial suture is obtained and in the presence of reliable asepsis, one can expect satisfactory and permanent results from the operative method here described.

142 York Street

ABSTRACT OF DISCUSSION

DR. H. W. CAVE, New York. There is a general impression that the cure of femoral hernia is a simple matter. This is due to the fact that the femoral hernia as a rule is small, that in proportion to the incidence of inguinal hernia there is one femoral hernia to every seventeen inguinal hernias, and to a prevalent belief that two mattress or purse string sutures closing the femoral canal, any kind of suture material being used, will effect a cure. This is erroneous. The anatomic arrangement of the femoral canal is often difficult and uncertain. The rigidity of three sides of the opening renders the uncertainty, the presence of the femoral vein on the lateral side necessitates caution in placing the sutures. Recurrences following the repair of a femoral hernia by either the superior or the inguinal route or the inferior or femoral route are approximately 5 per cent, this is a high percentage of recurrence. A recent analysis of the last hundred cases of femoral hernias in which operation has been performed at the Roosevelt Hospital has shown that over 90 per cent were single and not bilateral, 35 per cent either strangulated or incarcerated, 4 per cent of the strangulated variety necessitated resection of the bowel, 5 per cent were of the Richter variety, and 7 per cent were recurrent. Seven patients of the series died in the hospital. The principal feature in a radical cure is the obliteration of the neck of the sac at its highest point. The combined femoral and inguinal approach will prove, I believe, to effect a more certain cure, for from below a complete dissection from the surrounding structures can be carried out and from above eversion and a much higher obliteration of the neck are obtained. The extensive fascial repair advocated by Dr. Payne should be reserved for recurrent femoral hernias. To advocate making this extensive procedure a standardized one for every type of femoral hernia seems somewhat risky, for the operator who only occasionally employs the large Gallie or Kountze needle may puncture or tear the wall of the femoral vein, thus getting into unnecessary difficulties. May I again emphasize that, no matter how snugly the canal is closed without high secure ligation

Fig. 7—Femoral canal obliterated. Inset A shows method of splitting free end of fascial suture. Inset B method of tying the square knot. Inset C the free end tied, turned back and further anchored with two stitches of silk or chromic catgut. The remainder of the closure consists of the routine steps of approximation of the different layers as one would do in any hernia operation in the inguinal region.

of the neck, the incidence of recurrence in femoral hernias will continue to be relatively high.

DR. F. W. BAILEY, St. Louis. I am not in favor of the closure from the femoral end. I believe that the closure obtained by a free exposure of the upper end of the canal offers less chance of recurrence. I also believe that the pressure incident to the introduction of a fairly large fascial suture

with the use of the large so called Gallie needle, is a little dangerous because of the proximity of the vein. On two occasions I have seen thrombosis follow suture of the lower area with catgut. Consequently I favor closure from above with anatomic exposure, using fascial suture. Most femoral hernias have a content that is resident. Many of them cannot be reduced satisfactorily. No hernia that is incarcerated or strangulated should be forcibly reduced and the opening closed without inspection from within the peritoneum. The combined incision in the skin, which gives a clear view of both the inguinal and the femoral canals is undoubtedly the most satisfactory. The recurring femoral hernia to me is the least welcome of all, but since I have been utilizing for fifteen years the entrance to the canal instead of the exit, getting a clear exposure of all the fascial structures, I have had a far less rate of return. Fifteen years ago my attention was called to the excellent presentation of Dr McArthur of Chicago, and since that time I have been using the fascial suture. One is inclined to use a large fascial strip, requiring a broad-eyed needle. My experience in the last eight or ten years has been to utilize a smaller needle and a narrower strip and it has been just as satisfactory. The only new point that I wish to mention is with reference to the incision, and that is that the anatomic approach should be very clearly identified. No needle should be used, as Dr Payne emphasized, without clearing the fascial structures and being sure that one is suturing fascia and not the tissues surrounding one of the important and dangerous attending structures. I have on a number of occasions been unable to utilize the local fascial area because of tension or because of a previous operation. On those occasions I do not hesitate to use the fascia lata strip, taking advantage of the newer method of Grace and others in obtaining the fascial strip without undue trauma to the leg. In industrial cases it is not wise to make an accessory incision in the leg without a thorough understanding beforehand.

CHANGES IN VAGINAL EPITHELIUM DURING PREGNANCY IN RELATION TO THE VAGINAL CYCLE

M EDWARD DAVIS MD

CHICAGO

AND

CARL G HARTMAN, PhD

BALTIMORE

Since the investigations of Hitschmann and Adler¹ on the cyclic changes in the uterine mucosa, other portions of the mullerian tract have been studied in an attempt to show similar physiologic activity. Novak and Everett have demonstrated in the human female that there are secretory cells in the epithelium of the fallopian tubes which undergo cyclic secretory changes. Seckinger and Snyder² noted that the spontaneous contractions of the fallopian tube became more marked and rapid in the mid and late intervals following ovulation. This activity was greatly diminished during pregnancy.

Dierks³ in 1927 published the results of his study of the human vaginal cycle. He obtained pieces of vaginal mucosa from about thirty women from whom he was able to obtain accurate menstrual histories. In his description of the vaginal epithelium he states that

it is composed of three layers—a basal layer, a functional layer and a cornification zone. Immediately after menstruation a gradual increase occurred in the thickness of the functional layer. About the middle of the interval a zone of cornification appeared, separating the functional layer from the basal layer. This layer consisted of dark staining cells having a tendency to form granules in the cytoplasm, with rather small dark staining nuclei. The general appearance was that of a narrow, darker staining band of cells interposed between the basalis and the functionalis, which Dierks called the intra-epithelial zone of cornification. With the onset of menstruation a marked destruction of the functionalis and the intra-epithelial zone of cornified cells occurred, so that the basalis was completely denuded at the cessation of menstruation. These rhythmic changes in the vaginal epithelium were under the same ovarian influences as the changes in the uterus.

Dierks' article aroused considerable interest, and many publications appeared in the literature discussing the possibility of a cycle in the vaginal mucosa of the human female. Stieve,⁴ Stemshorn,⁵ Lindeman, Kückens,⁶ Gisbertz,⁷ and others could not find typical cyclic changes in the vaginal mucosa. Stieve felt that the varying changes which he found were similar to those seen in other mucous membranes, such as in the mouth and pharynx. On the other hand, Keller,⁸ Pankow, Geist,⁹ and more recently Papanicolaou¹⁰ described cyclic changes in the human vaginal mucosa which can be followed and correlated with ovarian activity.

Stockard and Papanicolaou¹¹ gave added impetus to the study of cyclic phenomena in the vagina by their discovery of the vaginal smear method in the guinea-pig. Thus by a simple study of the cytologic content of the vaginal fluid it was possible to follow the rhythm of the sexual cycle. No longer was it necessary to sacrifice the experimental animal. This method was quickly applied to other rodents, particularly the rat, in which case the cyclic phenomena were distinctly visible and clear cut in the vaginal fluid content. It was hoped that similar methods could be applied to the higher mammals and primates. In the human female and in monkeys, in which menstruation is the striking phenomenon in the sexual rhythm, relatively little information has been gleaned from the cytologic studies of the vaginal fluid content.

The presence of a cycle in the vaginal mucosa of the higher primates has thus received considerable attention. One group of investigators has studied the vaginal mucosa proper removed at various periods in the cycle in an attempt to correlate these observations with changes in the uterus and the ovaries. Human material accurately identified as to the time interval in the cycle was difficult to obtain. It was almost impossible to

secure frequent specimens from the same individual. Another group has continued to study the cytologic contents of the vaginal lumen in the human being, the chimpanzee and the rhesus monkey, correlating such changes with the sexual rhythm. We have attempted to combine our study of the vaginal mucosa with that of the vaginal fluid content, as one is entirely dependent on the other, thus associating the whole process with the cyclic phenomena in the entire genital tract.

They breed readily and are physiologically normal. Ovulation is diagnosed by rectal palpation and when ever this is doubtful, by laparotomy. It is questionable whether human material can ever approximate such ideal experimental conditions.

Biopsies of the vaginal mucosa were made at weekly intervals on a large group of these monkeys, a lighted speculum especially constructed for this work being

Fig 1—Sections $\times 100$ of vaginal mucosa removed during menstruation showing typical cyclic activity on the part of the epithelium in the normal sexually mature monkey a first day of menstrual cycle b seventh day c twelfth day d twenty first day

MATERIAL FOR STUDY

In the human female and her near kin—the higher primates—menstruation has been the outstanding manifestation of sexual activity. In the rhesus monkey the periodic flow occurs at approximately the same time interval as in the human female. It is for this reason that the monkey becomes exceedingly desirable for studies of sexual physiology. The Carnegie colony of monkeys is ideally suited for this study in that they

used. These specimens were immediately fixed, embedded in paraffin, sectioned and stained by various methods. A small portion of each biopsy tissue was fixed in absolute alcohol for glycogen study. The specimens were removed from approximately the same portion of the vaginal mucosa, although other portions of the vagina were studied for comparison. A similar series of biopsies was made on eight animals during the entire period of pregnancy, as well as during the

postpartum period. In none of the animals did we have any difficulty because of this minor procedure.

The cyclic changes in the vaginal epithelium are striking, and while they are not as sharply defined in many respects they resemble those seen in the rodents (fig 1). The epithelium usually consists of the three layers described by Dierks in the human female. Immediately after menstruation the basalis begins to undergo marked activity. This is noted by a marked proliferation of

Fig 2—Intra-epithelial zone of cornification or Dierks' layer showing the granular character of the cells. $\times 600$

the basal layer of cells. These cells become cuboidal in type, are larger than usual, and stand out because of their better staining ability. The nuclei become larger, stain darker, and show an abundance of active mitosis. Instead of the single layer of cells, several such layers rapidly develop. The functionalis, which has not been completely lost in the previous cycle, begins to grow thicker, owing to an accumulation of cells from the basalis. The cells in this layer are not altered. These are the cells in which retrogressive changes have taken place and they will be lost in the sloughing process. The intra-epithelial zone of cornification, or Dierks' layer, becomes more pronounced as the period of ovulation is approached. This layer increases in thickness. The cells become compressed and stain deeply, although there is little cytoplasm. The nuclei are elongated and stain darkly in a homogeneous manner. Throughout this layer are numerous granules. They are of various sizes, not entirely confined to the cells, and stain with nuclear stains. These granules give the characteristic appearance to this layer (fig 2).

The activity of the basalis continues to the twelfth or fifteenth day, when ovulation usually occurs. At the time of ovulation the epithelium has attained its greatest thickness following which desquamation begins. This proceeds by a steadily increasing crumbling away of the surface cells from the functional layer. The cells crumble away individually, in groups and in entire

plaques. This process increases in rate as the menses approach but does not seem to be very marked during the actual flow. Rarely is the entire functionalis lost during this sloughing process. If it is, Dierks' layer may likewise disappear. As a rule, some of the functionalis is retained and Dierks' layer becomes less pronounced, consisting of fewer cells. During this process of desquamation the cells in the basalis remain inactive, mitotic figures are rare, and the basal layer of cells becomes very low and cuboidal in type (fig 3).

The wandering cells in the epithelium likewise undergo rhythmic variations. In that period of the cycle just before, during and immediately after the menses, leukocytes, chiefly of the polymorphonuclear variety, may be seen in the mucosa. These cells are abundant just beneath the epithelium and come in between the epithelial cells in columns, pushing the cells apart. They are best seen in the basalis, where they stain deeply and apparently are alive. They decrease in number as the functionalis is approached, in which layer they are less numerous and many are apparently dying. There is a progressive diminution until the ovulatory phase is reached, during which they are almost absent, but recur again toward the end of the cycle. The cause of this leukocytic exodus is not known. Hartman¹² does not believe that their function is caused by the digestion of cellular detritus in the

Fig 3—Section $\times 600$ of the upper portion of the functionalis showing the process of desquamation. The cells break away individually and in plaques appearing in the content of the vaginal lumen.

vagina, in that the majority are probably dead when they reach the lumen of the vagina (fig 4).

CHANGES DURING PREGNANCY

Steve,¹³ in his extensive work on physiologic changes in the genital tract during pregnancy, described the

¹² Hartman, C. Studies in the Reproduction of the Monkey *Macacus Rhesus*, with Special Reference to Menstruation and Pregnancy. Carnegie Inst. Washington, Pub. 433, 1932, pp. 1-161.

¹³ Steve, H. Das Schwangerschaftswachstum und die Geburtserweiterung der menschlichen Scheide. *Ztschr. f. mikr. anat. Forsch.* 3: 3, 1925.

changes in the vagina. He noted that a marked thickening of the vaginal mucosa occurred, which represented an active proliferation early in the stage and later a growth of the tissue cells. Toward the end of pregnancy the epithelium may reach a thickness of from 450 to 500 microns. This thickening was due chiefly to an edema of the cells and to a less extent to cell division. The individual cells became larger and the cellular bridges wider. He noted that the mitosis diminished after the fifth month, although the epithelium became progressively thicker. The vaginal mucosa was examined by Stieve immediately after delivery. He found that the functionalis had completely disappeared, that the basalis in some cases was likewise extensively destroyed, and that the remaining cells were flattened and pressed together. The extent of the loss of epithelium depended on the length of labor and its character. After a long hard labor only a single layer of

Fig. 4—Section $\times 600$ of vaginal mucosa removed on the twentieth day of the cycle showing typical leukocytic invasion of the epithelium.

cells remained in the basalis. In a few cases there was little change in the squamous epithelium. He ascribed all these extensive sloughings of the vaginal mucosa to the mechanical damage of delivery.

In our pregnant experimental animals the vaginal mucosa remained at about the same stage as seen at the time of ovulation. In some of the cases the functionalis was even more marked than in the normal cycle. Dierks' layer became unusually prominent, owing to an increased thickness of this layer and to an increase in the size of the individual cells. The basalis continued to show marked activity and the cells increased in number and in size. The nuclei stained darkly and numerous mitotic figures could be seen in many of them. Mitoses continued until the latter half of pregnancy, when they decreased in number and disappeared completely at the end of gestation. The functionalis continued to show marked desquamation of the superficial layers, such as is seen at the time of ovulation in the normal cycle.

This sloughing process continued at about the same rate until after the middle of pregnancy, when it increased in extent. In the functionalis there occurred very large abnormal appearing cells, some round or oval, others oyster shaped, and their nuclei were likewise round and large, and stained poorly. These abnor-

mal cells appeared singly and in groups, and probably represent the so-called "pregnancy cells" of Papanicolaou,¹⁴ to which we will refer again. After the middle of pregnancy the functionalis began to crumble away.

¹⁴ Papanicolaou G. N. Diagnosis of Early Human Pregnancy by the Vaginal Smear Method. *Proc. Soc. Exper. Biol. & Med.* 22:436-437 1925.

layer by layer, until it had completely disappeared. In the last weeks of pregnancy Dierks' layer, as well as a good portion of the basalis, likewise disappeared as the result of the more extensive desquamation. In the last weeks of pregnancy all that remained was a few layers of basalis of irregular thickness. On the surface there were present several layers of cells that were elongated in type and compressed with dark staining nuclei, which probably represented a semicornified layer (fig 5).

This loss of almost the entire vaginal mucosa is a most interesting phenomenon in that it does not represent a mechanical destruction due to the trauma of labor, as Steve would have one believe, but to some other unknown etiologic factor. It occurred long before the onset of labor and in those monkeys at term that were delivered by cesarean section in which no trauma to the vaginal mucosa could have occurred.

Following delivery the vaginal mucosa was gradually rebuilt to its normal three-layered appearance by the end of the fourth postpartum week. At this time the functionalis, the basalis and the intra-epithelial zone of cornification could be clearly seen. Following this complete restoration the rhythmic activity of the mucous membrane began again. We could not determine whether lactation had any effect on the restoration of the mucous membrane, for in only one case did the young nurse. In this monkey the postpartum restoration of the vaginal epithelium took place in the same way and during the same time interval (fig 6).

RELATIONSHIP OF OVARIAN ACTIVITY TO THE MENSTRUAL CYCLE

It seems certain that the periodic sloughing of the surface layer of the vaginal epithelium is associated with ovarian activity, probably in the same manner as in the case of the endometrium. In very young girls, before the onset of puberty, the vaginal epithelium consists of a basalis of only three or four layers of cells, which are entirely inactive. This is the typical juvenile epithelium in the young girl and the young monkey. With the onset of ovarian function the three-layered condition is quickly built up. Experimentally, this can be done by the use of theelin. Robert Lewis recently made use of theelin in the treatment of gonorrheal vaginitis in children. He was able to change the juvenile type of vaginal epithelium to the normal adult type by the use of estrogenic substance. As soon as the vaginal mucosa was thus changed, the infection disappeared.

Following the menopause, whether spontaneous or artificially produced, the vaginal mucosa likewise degenerates to the condition seen before puberty. Allen¹⁵ castrated monkeys and followed this retrogressive change in the vaginal mucosa. When it had been completely broken down so that the basalis consisted of only three or four layers of cells, he injected theelin and restored the normal adult type of epithelium. In one of our monkeys, castrated for one year, two weeks' treatment with amniotin likewise completely restored the vaginal epithelium to the normal active type (fig 7). Dierks¹⁶ recently reported that in a castrated young woman he was able to produce a good functional layer

in the vaginal mucosa with 9,000 mouse units of estrogenic substance. In all these instances it can be readily seen that the vaginal mucosa is directly under ovarian influence and as such it must be subject to the rhythmic activity seen in the other müllerian derivatives.

In some of our monkeys cyclic activity on the part of the vaginal mucosa could be demonstrated without the occurrence of ovulation. Anovulatory periods are

Fig 6—Sections $\times 100$ of vaginal mucosa removed during the post partum period showing a rapid restoration of the epithelium. At the end of the first month the epithelium has been restored to the normal three layered appearance. a thirteen days post partum, b twenty days post partum, c thirty two days post partum.

well known and are quite common in the rhesus monkey. Hartman¹⁷ has demonstrated this many times. During the summer months menstruation occurs regularly in the monkey without ovulation. The changes in the basalis and functionalis, however, are not as marked as when ovulation occurs. Apparently the threshold for

growth, periodic bleeding and vaginal desquamation are all different, although all these physiologic phenomena are dependent on ovarian activity

No sloughing of the functionalis occurred in a very long cycle in one of our monkeys. On examination a persistent atretic follicle was found. Apparently this follicle provided a continuous stimulus to the vaginal mucosa so that its normal three-layered appearance persisted for an unusually long time.

In another animal a period of amenorrhea extended over eighty days. During this time the vaginal mucosa had been torn down to the senile type, only three or four layers of cells remaining in the basalis. Here ovarian activity was definitely at a minimum.

Fig. 7—*a* section of vaginal mucosa removed from a monkey that had been castrated for one year showing the extensive destruction of the epithelium; only several layers of cells remain in the basalis. *b* section of vaginal mucosa removed from the same monkey after it had received injections of estrogenic substance over a period of two weeks showing the restoration of the vaginal epithelium and the marked activity of the basal cells.

COMMENT

The human female, as well as the monkey, exhibits cyclic activity of the vaginal mucosa as well as the changes during pregnancy, as described.

Papanicolaou recently reported a study of the sexual cycle in the human female as revealed by vaginal smears. He made daily studies of the vaginal contents in twelve women by means of carefully prepared smears. This histologic study was correlated with the cyclic activity in the ovaries of these women. He was able to follow a clear-cut cycle in the occurrence and predominance of the various desquamated cells. These cells were an accurate index of the various stages in the sexual cycle.

Ovulation could be determined with a fair degree of accuracy from the contents of the vaginal smears in all these women. At the onset of pregnancy there occurred a marked change in the vaginal smear. The cells and their nuclei became large, with large flat cells predominating early in pregnancy. As pregnancy advanced the cells became smaller and more compact. Highly differentiated forms of cells gradually appeared, some oyster shaped, others remaining round or oval, and were characterized as navicular cells. These cells were identified by Papanicolaou as "pregnancy cells." Leukocytes were unusually abundant. After the termination of pregnancy the vaginal smear undergoes typical modification as the result of extensive desquamation. The cells are distinctly of the outer basal layer, with round or oval forms. Many polymorphonuclear leukocytes are present, and erythrocytes are numerous.

The cellular content of the vaginal lumen is a true index of the changes that take place in the vaginal mucous membrane. However, practically all the epithelial cells found in the vaginal smears have been sloughed off of the superficial vaginal mucosa and are dead cells.

The significance of the extensive denudation of the vaginal mucosa just before labor is difficult to explain. Perhaps the greatly thinned out epithelial layer is better suited for the extensive stretching it must undergo during delivery. It seems, however, that it is a poorer barrier to infection than the normal, thick, three-layered mucosa. Whether the extensive sloughing present in the monkey is likewise present in the human female is still to be proved. We would infer that the same condition exists in the human female, according to the postpartum studies of Stieve, as well as the fact that physiologic sexual processes in the human female and the monkey are very similar. Possible endocrine influences may be present toward the end of gestation, resulting in extensive desquamation and destruction of the vaginal epithelium.

SUMMARY

The cyclic changes in the vaginal epithelium were studied in a large group of female monkeys at the Carnegie Monkey Colony by means of frequent biopsies. These rhythmic changes were coordinated with ovarian activity and ovulation.

We found that the epithelium attains its greatest thickness in the midinterval, consisting at this time of an active basal layer, an inactive functional layer, and an intra-epithelial zone of cornification interposed between these two, which we call Dierks' layer. Following ovulation, desquamation begins and proceeds by a crumbling away of the functionalis, which is usually not completely destroyed. Mitosis begins in the basalis on the first day of menstruation, becoming most marked near the time of ovulation, and then gradually subsides.

A cessation of ovarian activity, such as is seen at the menopause, or an abnormal ovarian activity definitely alters these physiologic changes.

Early in pregnancy the epithelium remains in the same state as is seen during ovulation, consisting of the typical three layers.

Desquamation of the functional layer continues throughout pregnancy but is increased progressively following the middle of pregnancy.

At the end of pregnancy only the basalis remains and is of irregular thickness, in many places of only three or four cells.

In the postpartum period the epithelium is rapidly restored to normal at the end of the first month.

Hormone influences are probably responsible for these phenomenal changes.

5848 Drexel Avenue.

ABSTRACT OF DISCUSSION

DR. F. L. ADAIR, Chicago. It is obvious from the work of Drs. Davis and Hartman that it is at least theoretically possible to build up the epithelium in premature females and in castrates and presumably in postmenopausal conditions. This theory has been corroborated experimentally and therapeutically. This fact may lead to the use of estrogenic preparations for therapeutic reasons in clearing up infection and degenerative changes in the vaginal tract. A word of caution, however, should be interjected because the action of these endocrine substances is not limited to the vagina, and damage may be done to other structures and endocrinal imbalance may occur. One should be especially cautious in the use of these agents in sexually immature females. The examination of vaginal epithelium secured by smears or biopsy may enable one to diagnose differentially between the vagina of pregnant and of nonpregnant females between ovulatory and nonovulatory phases. This may be helpful in determining the cause of sterility in a woman who menstruates. In other words one may be able to determine whether or not a sterile woman who has normal anatomic organs is sterile because of lack of the ovulatory function. These changes are undoubtedly related to the physiologic and protective function of the vaginal lining and may explain the tendency of certain vaginal infections to advance and recede with the menstrual cycle. They are doubtless related to the copulatory mechanism and particularly with the preparation of the vaginal tubes for parturition. One can only speculate with regard to the relation of the immunity of the vagina to infection that may be associated with these changes. The exfoliation of the superficial cells of the vaginal epithelium may well serve as a cleansing process removing pathogenic organisms contained in the vaginal tube and superficial layers of the vaginal epithelium. The leukocytic barrier laid down in the subepithelial layers in the premenstrual stage and during pregnancy may well serve as a barrier to bacterial invasion of the underlying tissue. The increased vascularization facilitates the mobilization of the defense troops through the blood and lymph streams. This work of Drs. Davis and Hartman is very fundamental and shows the cyclic changes in the vagina and may well be of great practical value as well as explain some of the pathologic changes and clarify some of the phenomena that have previously been noticed but not understood.

DR. M. EDWARD DAVIS, Chicago. I have only one suggestion and that is that more biopsy material be used in studies of the vaginal mucosa. It should not be difficult under local anesthesia to take a small specimen for examination. Many changes in the vaginal mucosa can thus be followed. I am sure that the changes in the vaginal epithelium in the monkey will be found also in the human female. In the monkey the periodic flow occurs at approximately the same time interval as in the human female. It is for this reason that the monkey is especially adapted for this study. We intend to make further studies of the vaginal epithelium in an attempt to correlate the changes in the vagina with those in the ovaries. No one has ever attempted to demonstrate cyclic changes in the cervix but since it is also a part of the mullerian tract it likewise must undergo cyclic changes. It is hardly possible that one portion of the mullerian tract will undergo cyclic changes without involving the entire tract. Therefore, further studies with the proper material such as biopsies from the monkey or the human female, will probably reveal cyclic changes in the cervix as well as in other parts of the mullerian tract.

Mycobacterium Leprae—In fact it must be stated today sixty years after Hansen first saw *Mycobacterium leprae* that there exists no absolute proof as yet that any investigator during all of these years has actually succeeded in cultivating *Mycobacterium leprae* in vitro—McKinley E. B. The Etiology of Leprosy. *Medium* 13:377 (Dec.) 1934.

THE NECESSITY FOR THE STANDARDIZATION OF THE TREATMENT OF BACILLURIA

ALBERT M. CRANCE, M.D.

GENEVA, N. Y.

Considering the fact that modern urology has in general made great strides forward during the past two decades, there is still a wide discrepancy within the profession regarding the management of urinary infections, particularly those infections which are due to the colon bacillus group. This discrepancy should actually not exist. Its remedy is obtainable only by effecting some definite standardization in the management of bacilluria in general. My purpose in this paper, therefore, is to summarize briefly the reasons why such a therapeutic standardization is possible as well as advisable.

Needless to say, it has apparently not yet been learned that there is no urinary antiseptic which eliminates the colon bacillus from the urinary tract. Drugs, therefore, are of little value in treating this infection.

It must furthermore be borne in mind that urinary infections due to *B. coli* rarely ever disappear spontaneously. It was only a few years ago that one of the great urologists said that, in his opinion, when a patient develops colon bacillus infection in the kidneys he is bound to go to his grave with the kidneys still infected. Today, since advances in the management of bacilluria have become so obvious, this statement is decidedly out of order. Approximately 80 per cent of colon bacillus infections in the urinary tract can be completely eliminated by conscientious, practical methods of therapy.

As early as 1924 I¹ reported a small series of cases in which complete recovery occurred by the use of autogenous vaccine, given in rather large doses at five day intervals over a period of from eight to twelve weeks. Many physicians have little use for vaccines. I am not an exception to this belief. However, so far as *B. coli* infections are concerned, it is perhaps one of the most valuable aids to date.

Continuing to work out more effective measures, because it was obvious that not every case would respond to one form of treatment alone, I began to wonder why nearly all these cases showed infection in one or both kidneys. In fact, all cases were thoroughly studied on the cystoscopic table, and in more than 90 per cent the infection was found to originate above the bladder. Why should this be true? Why also did so many of these cases give histories of chronic constipation, or in fact some intestinal upset, such as diarrhea, prior to the appearance of cystitis symptoms? The reason is, I believe, that the colon bacillus, whose natural habitat is in the colon, is by virtue of its increase in numbers politely invited to seek a new residence and, by gaining entrance to the lymphatic system, finds its way to the kidney, where it is known to become a pathogenic, pus producing organism. With this theory firmly in mind the treatment then became more of a matter of treating the colon, the focus of infection. It is quite evident that if the number of *B. coli* in the intestinal tract can be reduced to somewhere near normal the organisms will cease leaving it to go elsewhere.

Read before the Section on Urology at the Eighty-Fifth Annual Session of the American Medical Association, Cleveland, June 14, 1934.
1. Crance, A. M. Treatment of Colon Bacillus Infections of the Upper Urinary Tract with Autogenous Vaccine. *M. J. & Rec.* 110:393 (March 19) 1924.

Three methods may be used, and in fact all three methods should be used, in attacking the problem of correcting the focus first, by daily enemas, second, by changing the intestinal flora each two weeks with a sudden change in diet—i e, two weeks high protein, two weeks high fat and two weeks high carbohydrate, third, by the daily use of a good acidophilus preparation, preferably not in milk. These, together with the aforementioned autogenous vaccine, constitute four important measures, which I have termed the "four-point treatment." As reported in 1928,² it gave 80 per cent satisfactory results, and this percentage has remained the same. This method of treatment was used long before the various types of the colon group were differentiated

TYPES OF BACILLURIA

Bacillus coli constitute approximately 80 per cent of all urinary infections, excluding of course the gonococcus. Today it is definitely known that two distinctly separate types of *B. coli* exist, namely, the *Escherichia* and the *aerogenes* varieties. These constitute nearly all the cases of bacilluria. Others, which occur far less frequently, are *pseudomonas* (*B. pyocyaneus*) and *B. proteus*.

Of chief concern in this paper is the management of the *B. coli* group. First of all, it must be borne in mind that this discussion does not deal with cases presenting surgical complications such as perinephric abscess or surgical pyonephrosis but rather it is to deal with the type of case in which treatment is considered medical in character.

IMPORTANCE OF DIAGNOSIS

Diagnosis is of primary importance. Samples of urine for culture should always be collected by catheter in the female, and in the male by careful cleansing of the meatus prior to voiding in a sterile container. Cultures will show practically all types of bacillus infections and the coccus group such as staphylococci and streptococci, tubercle bacilli excepted. When *B. coli* is found, usually in pure culture, the laboratory should go further and subculture the specimen to determine which type is present. A very simple method may be used for determining this. *Aerogenes* produces gas within forty-eight hours in saccharose, whereas *Escherichia* does not. Both types form gas in lactose. It is very important, as I will try to point out, to know which type is present before any outline of treatment is attempted. As already stated, I have obtained approximately 80 per cent successful results in the treatment of *B. coli* infections during the past ten years by the so-called four-point treatment. This method yields results in the *aerogenes* type practically as well as it does in the *Escherichia* variety.

Clark,³ formerly of the Mayo Clinic, and also Helmholtz⁴ have shown in several recent reports that about four out of five patients presenting infection with *Escherichia coli* will completely recover by the ketogenic diet treatment. During the past two years, I have been able to obtain approximately the same percentage of recoveries in this type, using the ketogenic regimen. The principle of the ketogenic treatment probably needs

little explanation, excepting that the work of Fuller of England has shown that a specific agent (1-B-hydroxybutyric acid) is produced in a ketone urine and that this agent destroys the colon organism. A recent editorial in THE JOURNAL⁵ also reviewed in an interesting manner the action of this specific agent. The diet also strives to yield a urine with a pH somewhere below 5.1. Colon bacilli are destroyed in an acidity of from 5.1 to 4.6 (Normal urine averages approximately from 6.8 to 5.8). Clark also obtained satisfactory results in seven out of twenty-one cases presenting the *aerogenes* type. In ten cases of the *aerogenes* type that I treated, the ketogenic regimen failed in each instance. Therefore, with one worker showing only one out of three patients recovered, and another showing no recoveries, why should the ketogenic diet be considered as a method of choice in treating the *aerogenes* type?

This is exactly where the standardization of definite therapy enters the picture. Since the *Escherichia* type of *B. coli* responds to both the ketogenic regimen and the four-point treatment with approximately equally satisfactory results, one has the choice of either. The ketogenic diet is much the quicker method if it produces the result, from ten to twenty days usually being sufficient. Against the ketogenic diet is the fact that hospitalization is necessary, or at least the patient must go to the hospital for meals, if the utmost cooperation is to be obtained. On the other hand, if the ketogenic treatment fails in this type, the other treatment may be resorted to (cases 7, 8 and 9). Conversely, patients failing to recover with the four-point treatment may completely recover under the ketogenic regimen. I have had one such case (12). Generally speaking, therefore, in infections with *Escherichia coli* the ketogenic diet, when possible to carry out conveniently, is the method of choice. The other method can always be resorted to if necessary.

For reasons previously stated, the ketogenic diet, in my opinion, is not at all indicated in the *aerogenes* type of *Bacillus coli* infections. The percentage of successful results has been too low to warrant the advisability of submitting patients to the expense of hospitalization or dietary measures. The *aerogenes* type decidedly calls for the four-point treatment. My results with this type have been entirely satisfactory, and in fact I feel that the *aerogenes* type definitely contraindicates the use of the ketogenic regimen. It has occasionally been necessary to repeat the course of treatment, persistence, until complete recovery, is essential to its success.

Pseudomonas (*B. pyocyaneus*) infections respond exceptionally well to the ketogenic diet, as do the majority of the remaining types of organisms found less frequently in bacillurias. In the *pseudomonas* infections, Clark⁶ was able to obtain sterile urines from thirteen out of fourteen patients treated.

AUTHORS FOUR-POINT TREATMENT

1 Autogenous vaccine, made up 1 000 million per cubic centimeter, is given intragluteally at five day intervals, beginning with 0.5 cc and increasing each subsequent dose by 0.5 cc until the dosage of 2 cc is reached. Usually a course of twelve injections is given.

2 Daily enemas are given. The soapsuds enema is used, the size being increased up to 2 to 2½ quarts. This portion of the treatment helps to eliminate an excess of colon bacilli from the intestinal tract, which is the focus of infection.

3 Previous work has shown that *Bacillus acidophilus* definitely aids in changing the intestinal flora and also that it aids the intestinal tract in its function of elimination. It is prescribed in liquid culture form because in milk it would interfere with the change in diet mentioned in the fourth item.

4 Two weeks of high protein diet, two weeks of high fat diet and two weeks of high carbohydrate are given for the purpose of changing the intestinal flora, which in turn decreases the number of colon bacilli in the colon. It is occasionally necessary to continue on with this diet if the urine still shows positive cultures at the end of the first six weeks.

GROUP ILLUSTRATIONS BY TYPICAL CASE HISTORIES IN BRIEF

The following three cases are used as examples of treatment prior to the time when any differentiation of type of colon bacillus was made.

CASE 1—Mrs C W, aged 53, admitted Dec. 23, 1927, complained of frequency and burning micturition, with considerable dysuria and recent hematuria. Cystoscopy revealed a marked purulent cystitis. The kidney samples in this case, however, were negative. Culture from the bladder showed the colon bacillus. She was placed on the four-point treatment as described. Ten weeks later there was freedom from all symptoms; the urine was negative for pus cells, and culture was sterile.

CASE 2—Mrs J K, aged 30, admitted Dec 5 1927 with an early pyelitis of pregnancy, complained of marked frequency and burning micturition, with marked pain in the right part of the back, encircling the abdomen downward. She had a temperature of 103 F. Cystoscopy revealed thick purulent urine from the right kidney, which showed the colon bacillus on culture, the left side was clear and sterile on culture. The right kidney pelvis in this case was irrigated on only one occasion with 1 per cent mercurochrome. She was placed on the four-point treatment and was free from all symptoms within two weeks. In twelve weeks she was reexamined. The urine was found clear and sterile and she later went on through delivery without further trouble.

CASE 3—A. H., a man, aged 26, admitted Feb 14, 1925, was acutely ill, with marked pain in the right kidney region, a temperature of 105.5 and a history of chills for the past two weeks together with bloody urine and frequency, although he had had some bladder irrigations for the past three months. He had passed clots of pus and blood the past week, with considerable referred pain to the penis. This case is especially interesting because the bladder was so terrifically infected that it was utterly impossible to locate the ureteral orifices and, consequently, passing a catheter for drainage or lavage of the right renal pelvis was impossible. Therefore this could not be used as a factor in treatment although it was evident that the source of the infection was in the right kidney. The patient was given the four-point treatment immediately and in three days the temperature had dropped to normal. He was discharged from the hospital two weeks after admission free from symptoms but with a pyuria still present. He continued with the four-point treatment at home with the vaccine being administered each five days by his home physician. Twelve weeks later he was perfectly well. The urine was free from pus cells and the culture no longer showed growth of colon bacilli.

The following three cases of *Escherichia coli* infection illustrate beyond doubt the splendid results obtainable with the ketogenic diet.

CASE 4—W C, a man, aged 52, admitted Sept 19 1932, complained of marked weakness, chills, loss of appetite, marked

frequency, urgency and burning micturition. The cystoscopic diagnosis was severe purulent cystitis. Kidney samples were negative. Bladder culture showed a heavy growth of *Escherichia coli*. The ketogenic diet was started September 20. The same day the urine pH was 6.3. September 21, 5.5, September 22, 5.2, September 23, 24, 25, 26 and 27, 5.1. On September 27, seven days after treatment was begun, an examination of the urine showed it to be free from pus cells and sterile on culture. There has been no recurrence to date.

CASE 5—Mrs T C, aged 47, admitted Nov 10, 1932, complained of marked frequency, urgency, painful micturition and hematuria at the onset one week prior. Cystoscopy showed a very marked severe generalized cystitis. Both kidneys and bladder cultures showed *Escherichia coli*. The ketogenic diet was begun November 11, with a pH of 5.8, subsequently decreased as follows: November 12, 5.3, November 14, 5.1, November 15, 5.0, November 16, 4.9, November 17 5.0. Culture made November 17, the seventh day of treatment, showed the urine to be free from pus and culturally sterile. The symptoms had entirely subsided and the patient was discharged as recovered. There has been no recurrence and the culture has remained sterile.

CASE 6—Mrs M B, aged 56, admitted June 21, 1932, complained of frequency and burning micturition, which had been present several months. The diagnosis was bilateral chronic pyelitis and cystitis due to *Escherichia coli*. The urine showed ++++ pus cells. The ketogenic diet was begun June 27 and ended July 8. The lowest pH obtained during this time was 5.2, although tests had on several occasions daily showed ++++ diacetic acid and acetone. All symptoms had disappeared and the urine was free from pus cells at the time of her discharge July 9, 1932. She has remained perfectly well.

The following three cases illustrate the successful use of the four-point treatment after failure with the ketogenic diet in the *Escherichia coli* type.

CASE 7—Miss L C, aged 35, admitted May 5, 1933, complained of frequency and urgency which had been present since January. She also complained of severe constipation. Examination by her home physician had revealed ++++ pus in the urine, and various kinds of internal medication had been prescribed with no relief. Examination revealed a primary cystitis very severe in character, but both ureteral samples were clear and sterile. The bladder urine showed a heavy growth of *Escherichia coli*. The patient remained in the hospital for three weeks under ketogenic treatment with no relief and with no change in the pyuria. She returned to her home city after having begun the four-point treatment. The treatment was continued by her home physician until early in July, at which time she had recovered symptomatically. She returned, July 31, at my request, for a culture of the urine. It was found free from pus and sterile. Incidentally, the patient returned for another check up May 12, 1934, and again the urine culture was sterile.

CASE 8—W G, a man, aged 69, admitted March 6, 1933, complained of marked frequency, with burning and some dribbling. The attack had started about a week prior, during which time he had been at home under the care of his family physician. There had been chills and fever and considerable hematuria for the first five days. Examination of the prostate was entirely negative. Cystoscopy revealed a severe generalized cystitis and samples from both kidneys showed pus and cultures were positive for *Escherichia coli*. The ketogenic diet yielded a sterile culture and a complete disappearance of pus cells in seven days. The diet was continued a few more days and the patient was discharged. Within two days there was a recurrence of symptoms and the culture was again positive. March 27 he was again placed on the ketogenic diet for three weeks, taking his meals as an outpatient at the hospital. There was no improvement in the pyuria and cultures remained positive. He was then given the four point treatment, which he followed very cooperatively for several weeks, and on July 10 the culture no longer showed any colon bacilli and the urine was entirely clear. This patient has had no further recurrence and appears to be in excellent health.

CASE 9—Mrs B B., aged 37, admitted Jan 11, 1933, complained of rather severe pain in the right side of the abdomen and back, which had begun three days prior to admission. The symptoms suggested right ureteral calculus but examination revealed a right pyelitis with a mucopurulent cystitis due to *B coli* infection, *Escherichia* type A. A right pyelogram showed definite clubbing of all the calices, with a dilatation of the renal pelvis. There was also evidence of a slight kink at the right ureteropelvic juncture. This was not surgically treated. The ketogenic diet was begun, and on February 2 there had been no improvement in the pyuria and cultures were still positive. The patient was discharged and placed under the care of her family physician, who carefully followed out the four-point treatment. March 4 a culture was made on a specimen of catheterized urine and it was found to be sterile. She had remained perfectly well without further pain or recurrence of the pyuria.

The following two cases are used to illustrate typical examples of results obtained with the four-point treatment in the aerogenes type. (In this type I believe that the ketogenic diet treatment is definitely contraindicated.)

CASE 10—Mrs L D., aged 40, admitted May 28, 1932, had severe right renal colic chills and fever. There had been several severe attacks during the week prior to admission. Examination revealed a right pyelitis ++++ pus cells and cultures of *B coli* (aerogenes type). She was discharged May 30 and began the four-point treatment. She received a total of twelve injections of autogenous vaccine over a period of ten weeks at the end of which time she was perfectly well and stopped all treatment. August 18 a sterile culture of urine was obtained. There were no pus cells present.

CASE 11—Mrs A D., aged 42, admitted Jan 26, 1933, complained of frequency with nocturia from one to five times and severe pain in the bladder region and dysuria. The present trouble had been gradually getting more severe in character since its onset, several weeks prior. Cystoscopy revealed severe chronic generalized cystitis, ++++ pus and aerogenes type *B coli* from the bladder, and ++ pus cells with positive culture from the right kidney. Examination of the left kidney was negative. The four-point treatment was begun immediately. All symptoms had disappeared by April 10 at which time a catheterized bladder sample was free from pus cells and cultures were sterile.

The following case is one in which the four-point treatment resulted in a pus free urine but not a sterile urine on culture. However, hospitalization with the ketogenic regimen resulted in a sterile culture in nine days.

CASE 12—Mrs S S., aged 40, seen Dec 13, 1932, complained of frequency urgency and burning micturition with marked pain following voiding. The trouble had begun one week prior, at which time there was hematuria. Six months before examination she had a similar attack and again another attack in September with a definite bladder irritability existing constantly. The present attack was probably an acute flare up of a previously existing bacilluria. The culture showed a heavy growth of *Escherichia coli*. The four-point treatment was carried out until May 1, 1933 at which time all symptoms had disappeared and the urine was clear and free from pus cells. The culture, however, showed a heavy growth of *Escherichia*. Although she felt perfectly well, she was willing to enter the hospital and take the ketogenic treatment in an effort to obtain a sterile urine. Nine days after the ketogenic treatment, cultures of the urine were negative. One culture has been taken since, which again showed no growth. She has continued to remain perfectly well.

SUMMARY OF CASE REPORTS

I have chosen the foregoing examples from a series of more than 250 cases of *B coli* infections, simply to illustrate the principle outlined in the paper, which

is directed toward the standardization of therapy. An effort has been made to show that the four-point treatment, although occasionally requiring several weeks, yields a high percentage of satisfactory results in either the *Escherichia* or the aerogenes type. It has also been shown that the ketogenic regimen is indicated only in the *Escherichia* type, and when results are obtained they are usually quicker than with any other method of therapy. One group of cases illustrates that it has been necessary, in several instances, to complete the treatment by this method after the ketogenic diet had failed.

SUMMARY

The first remark should deal with the importance of bacilluria. Too often is this type of case "passed up" as something inconsequential, to be treated only with urinary sedatives or the supposedly antiseptic preparations. Too often does the physician believe, because the symptoms subside under these remedies, that he has cured his patient. *B coli* infections especially may subside sufficiently to warrant this belief. Actually, however, the infection goes on, and sooner or later a "flare up" occurs, at which time it will erroneously be termed a "recurrence." It is not a recurrence in the true sense but rather an acute exacerbation, simply because the case was not carried along to complete recovery at the time of the previous treatment. A cure depends on three things—no more, no less. These are freedom from symptoms, a urine free from pus and an entire absence of bacilli on culture. The culture must be sterile.

CONCLUSIONS

The following conclusions are directed entirely to the standardization of the treatment of bacilluria.

- 1 The physician should have courage enough to discontinue the use of oral medication with urinary antiseptics. It has previously been proved that they will not yield a sterile culture of the urine.

- 2 *Bacillus coli* cultures must be subcultured, since the treatment depends on the type, whether aerogenes or *Escherichia*.

- 3 *Escherichia coli* infections heal very satisfactorily under the ketogenic diet in fully 80 per cent of the cases. When this fails, the four-point treatment is indicated. It is well to remember that the two treatments yield equally good results but that the ketogenic treatment is usually somewhat quicker in effecting a cure.

- 4 In the aerogenes type of *B coli*, the four-point treatment appears to be by far the better method of attack. It will require from eight to twelve weeks of persistent effort, on the part both of the physician and of the patient.

- 5 *Pseudomonas*, and other less common types of bacilluria, apparently respond best to the ketogenic treatment.

- 6 The stubbornness of *B coli* infections in general being realized, a complete cystoscopic study of each case including differential function, elimination of ureteral strictures, and the like, should be made. Pathologic changes that will interfere with the treatment should be known in the beginning. It would seem more advisable for the physician to make such a study before treatment is instituted rather than to find out later why the treatment failed.

A SIMPLIFIED TREATMENT OF
BACILLURIA

ANSON L. CLARK, M.D.

AND

BERT F. KELTZ, M.D.

OKLAHOMA, CITY

From the work of William Mansfield Clark¹ it has been shown that it is practically impossible to increase the acidity of the urine sufficiently by the oral administration of any drug to inhibit entirely the growth of the colon bacillus. Because of this it was decided to try the effect of altering the food intake. Barborka² suggested that the ketogenic diet, which had been used originally by Wilder in the treatment of epilepsy, produced an acidity of the urine considerably above the normal. Previously, Johnson³ had placed several patients with a bacillary infection of the urinary tract on the ketogenic diet. He noted some improvement in their condition, but the patients were too ill to allow a thorough test of the treatment. About this time Helmholz had noted that the urine of a patient on the ketogenic diet for the treatment of epilepsy remained clear and apparently sterile, although it had been voided into an unsterile vessel and allowed to stand for a number of days.

To a patient who had returned to the Mayo Clinic a number of times for treatment of a persistent bacillary infection of the urinary tract belongs the real credit for making the ketogenic treatment available to the other sufferers of this ailment. During his fourth trip to the clinic in fourteen months he announced that he would stay until his condition was entirely relieved. At this visit, as before, many different types of treatment both local and oral were applied, with only temporary periods of improvement. The culture of the urine showed the infecting organism to be the colon bacillus. July 21, 1931, the patient was placed on the ketogenic diet. In five days his symptoms of burning, frequency and urgency of urination were relieved. In twelve days a culture of the urine revealed the absence of the colon bacillus. Refusing to believe in his good fortune, because of his many periods of temporary relief in the past, he insisted that he be allowed to remain on the diet for ten more days. This patient has been followed for over two years since discontinuing this type of treatment and has not had a recurrence of the urinary tract infection. In August 1931 another patient was placed on the dietary treatment with very satisfactory results. Subsequently, Helmholz put several children who were suffering from infections of the urinary tract on the ketogenic diet and he also obtained excellent results.

In October 1931 one of us reported these first two cases at the staff meeting of the Mayo Clinic,⁴ and following this Helmholz presented his results. Since that time, the reports of a number of investigators⁵

who have used the ketogenic treatment in chronic urinary infections leave no question as to its definite therapeutic value. We wish to reiterate that urinary sepsis is frequently concomitant with other urologic conditions, such as obstructions, tumors and calculi. Necessarily, the management of these cases must include the early elimination of any such complications.

Up to the present time the ketogenic treatment has required the cooperation of a trained dietitian. In many cases this has necessitated hospitalization of the patient. Robb,⁶ reporting a carefully controlled series of cases, says in his conclusions: "The results suggested that the ketogenic diet was an unsuitable form of treatment for outpatient departments." Since accumulated data have shown a definite increase in satisfactory results obtained in this type of treatment compared with those of other types of therapy, it would seem essential to simplify it to permit its application to office practice and outpatient departments.

To do this, we present the following simplified ketogenic treatment, which has been shown from our experience to be applicable to office practice. The diet may be prescribed without detailed dietetic knowledge by the physician and can be prepared in the average home without special dietetic supervision. The menus are so arranged that, regardless of the items selected from the different groups, the daily intake of food will consist of carbohydrates 15 to 20 Gm., protein 35 to 50 Gm., and fat 300 to 325 Gm., with a ketogenic-antiketogenic ratio of approximately 4 to 1. The vitamin deficiency need not be considered, since the patient will be on the diet only a short period of time.

The simplified diet consists primarily of cream (40 per cent fat), mayonnaise, butter, eggs, bacon and vegetables containing 3 per cent carbohydrate. In group A are combinations of eggs and cream, group B gives a number of recipes for salads, group C is desserts, and group D contains the beverages that may be taken. The various items in each group have approximately the same carbohydrate, protein and fat content. The daily menu instructs the patient from which group selections are to be made for each meal.⁶

How is the ketogenic diet effective in eradicating urinary sepsis? Two conditions are necessary. Sufficient concentration of ketone bodies must be present in the urine coincidental with an acidity of the urine of p_{H} 5.2 or less if satisfactory results are to be obtained. Fuller⁷ has shown that levorotatory beta-oxybutyric acid is the ketone body producing the greatest bacteriostatic effect. Helmholz and Osterberg⁸ were able to demonstrate the bactericidal effect of urine with a p_{H} of 5.2 and a beta-oxybutyric acid content of 0.5 per cent. Recent work by Clark, Moore and Harrell,⁹ however, indicates that at a p_{H} of 5.0 and a beta-oxybutyric acid content of the urine up to 1.5 per cent the effect of the urine is not sufficiently bactericidal to inhibit entirely the growth of the organisms. As the average beta-oxybutyric acid content of the urine of an adult patient on the ketogenic diet will not exceed a concentration of 1.2 per cent and the average acidity of the urine will not be greater than p_{H} 5.0, it is probable that the action of the ketogenic treatment is one of bacteriostasis. It is important that this bacteriostatic

II One choice from group D		III One choice from group C	
III 8 slices of thin crisp bacon or		III One choice from group D	
4 tablespoonfuls of cream			
(40% fat)			

In some cases it may be impossible for the patient to have specially prepared menus. Satisfactory results will be obtained if one and one half pints of cream (40% fat) and six eggs are prescribed as the daily food intake. The recipes and suggestions in groups A and D may be used.

Important Instructions to Patient

- 1 Satisfactory results cannot be obtained unless this diet is followed absolutely as outlined. Even the smallest deviations will ruin the chance for success of this treatment.
- 2 No food or beverage other than that listed is to be taken.
- 3 Water may be taken in moderate quantities as desired.
- 4 The chewing of gum or tobacco is not permitted. Smoking is allowed.
- 5 No cathartics are to be used other than liquid petrolatum or bitter casera. Magnesium magna or other sweet cathartics may cause failure.
- 6 Do not take any medicines unless prescribed by the physician. It may conflict with the diet.

* It is of utmost importance to use extra thick cream containing at least 40 per cent fat. The average whipping cream is only about 32 per cent fat.

Recipe for mayonnaise

Egg	1
Vinegar	2 tablespoonfuls
Salted oil	1 pint
Salt	2 teaspoonfuls
Mustard	1 teaspoonful
Pepper	few grains

Have ingredients cold. Beat egg until stiff. Add dry ingredients. Add oil drop by drop beating constantly. Thin with vinegar to the desired consistency.

three to five days. At the end of ten or twelve days, whether or not the results have been satisfactory, a mixed diet should be resumed. Several short courses of the dietary treatment are preferable to one long course. Certain patients will put through the ketone products in the urine much more quickly than others. To maintain a continuous ketonuria it may be necessary to space the intake of fat more evenly. This may be done by supplementary feedings of cream (40 per cent fat) between meals, especially between the evening meal

and breakfast. During the treatment the physician should not be alarmed if the patient is nauseated. It may cause the patient to miss one or more meals without interfering with the desired results. Experience has shown that normal exercise and activity will lessen anorexia. Only the normal fluid intake should be prescribed. To force fluids will lessen the bacteriostatic effect by diluting the ketone bodies in the urine.

DAILY TESTS

Evidence of ketosis is based on the test for diacetic acid in the urine. If it is present, equal parts of a 10 per cent aqueous solution of ferric chloride and the patient's urine give a port wine color. It must be remembered that a patient who is taking acetylsalicylic acid will give a false positive test. The tests for diacetic acid and acidity of the urine should be made daily. Herrold⁹ suggests a most useful procedure for an approximate measure of the acidity, which may be quickly and easily done in the office. To 20 drops of the patient's urine, one drop of 0.04 per cent solution of chlorophenol red is added. If the color of the urine remains the same, it is safe to assume that the acidity is pH 5.2 or less. After the addition of the indicator, if the solution becomes faintly pink or red, the acidity is above pH 5.2 and indicates that further measures for acidification of the urine will be necessary to obtain satisfactory results.

A stain of the urine sediment should be made every other day. After three tests have shown that the bacillus is apparently no longer present in the urine, the treatment may be discontinued. The final test, of course, is whether or not the bacillus is found in the urine after the patient has returned to a general mixed diet and the ketone bodies have disappeared from the urine. When one can follow the progress of the patient conveniently, microscopic examinations of the urine will eliminate the need for cultures as the final test of a satisfactory result.

DRUGS

In prescribing the simplified ketogenic diet, we have found it advisable to give no oral medication until ketone bodies have appeared in the urine. At that time, if the acidity of the urine is above pH 5.2, it may be advisable to give ammonium chloride orally to increase its acidity. Ammonium chloride 12 drachms (47 Gm) in 8 ounces (240 cc) of water makes a solution of which 2 fluidrachms (8 cc) in a glass of water may be given after each meal and at bedtime. This medication may upset the gastro-intestinal tract, in which case 15 grains (1 Gm) of the drug is given every two hours for six doses. The 15 grains is prepared in the form of two enteric coated tablets, each of 7½ grains (0.5 Gm).

In some cases tests will indicate that sufficient acidity has developed but that the percentage of ketone bodies in the urine is insufficient to produce the necessary bacteriostatic action. In such an instance, the oral administration of methenamine may increase the bacteriostatic power of the urine to a point at which the organism will be eliminated.

LOCAL TREATMENT

Hydrostatic lavage of the bladder with 1:2,000 solution of acetic acid or 1:8,000 solution of potassium permanganate may be instituted, but excellent results have

⁹ Herrold, R. D. and Ewert, E. E. A Simplified Test for the Determination of Approximate Acidity of Urines. *Urol. & Cutan. Rev.* 37: 607 (Sept.) 1933.

been obtained without lavage, particularly in women. It should be remembered that the mechanical and chemical irritation of the catheter and lavage may offset the relief afforded by the ketogenic treatment. In male patients, a gentle massage of the prostate gland every second day is given to eliminate thus as a focus of infection. In a number of cases in which there are resistant or recurring infections, urethroscopy may reveal dilated prostatic ducts leading from small chronic abscesses. As organisms from these foci may constantly reinfect the urine, drainage from such regions should be obtained by cystoscopically enlarging these ducts, as described by Thompson¹⁰. In women, urethral cysts and small infected urethral glands should receive careful attention.

Frequently the coccic type of infection may be associated with the bacillary type. In these cases a short course of neosarsphenamine may be helpful, an intravenous injection of 0.3 Gm is given every five days for from four to six doses.

In prescribing the ketogenic treatment it must be remembered that the bacteriostatic agent must pass through the kidney. Poor renal function, particularly if unilateral is a contraindication for this type of treatment. In carefully observed cases it has been found that the ketone bodies will be largely excreted through the kidney with good function. There are two groups of cases for which we have no explanation as to the possible reasons for unsatisfactory results. One group will not develop a ketonuria, while in the second group the p_H of the urine remains high, although large doses of some acidifying agent are administered.

SUMMARY

Applied in short courses, the simplified ketogenic treatment of bacillary infections of the urinary tract may be prescribed by the physician in the office or in the outpatient department with very satisfactory results.

119 North Broadway

ABSTRACT OF DISCUSSION

ON PAPERS OF DR. CRANCE AND DRs CLARK AND KELTZ

DR WILLIAM P HERBST JR Washington D C Both presentations have outlined excellent plans of treatment. Dr Crance has presented a combination type of treatment consisting of the alternating forms of diet, treatment of the colon and vaccines which in his hands has unquestionably been very satisfactory. I haven't had any experience with this treatment. It has been generally accepted that lavage of the colon is satisfactory in aiding in the treatment of chronic urinary infections even when dependence is placed on urinary antiseptics. Specificity of the vaccine used is a rather important phase of the problem. To retain specificity cultures should be young and made up into vaccine very rapidly so that they will have a more satisfactory effect. In regard to the ketogenic diet as outlined by Drs Clark and Keltz the greatest value is in widening the number of patients to which the treatment is applicable. They have presented an ambulatory treatment that can be outlined in the office and followed in the home. Any treatment that will allow the discontinuance of instrumentation of the bladder is a tremendous boon in itself. That is one thing which this ketogenic regimen does. I want to say something about the types of relative obstruction that cannot be remedied by any known means. I refer to cases in which there are large dilated kidneys and ureters as a result of neurogenic or chronic infection. The drainage in these cases cannot possibly be improved and for that reason they have not responded well to the accepted forms of treatment. In this particular group it is certainly a great boon to be able to clear up the infection. How does the ketogenic diet produce its effect? Is

it due entirely to the change in the p_H and to the changes in the percentage of beta-oxybutyric acid? There are some patients in whom the p_H fails to come down to the desired point, and there is no appreciable amount of the beta-oxybutyric acid, but who nevertheless are definitely relieved and improved. There must therefore be some other factor in the problem besides the p_H and the beta-oxybutyric acid. I don't know whether it is on the basis of vitamin content of the diet or not but I do feel strongly that there must be some other factor.

DR CLIFFORD J BARBORKA Chicago There is a question in my mind whether the bactericidal property from the beta-oxybutyric acid alone sterilizes the urinary tract or whether this, combined with other factors from a ketogenic regimen, acts as the sterilizing agent. I would emphasize two points: first not to be too critical nor on the other hand too enthusiastic in the possible application of diet in the treatment of disease. There are a great many possibilities that are going to be developed from the studies of the influence of food and its possible interrelations on the tissues of the body. Second, if the simple qualitative method such as Drs Clark and Keltz have presented can be taught to patients in office practice so that it will produce an adequate ketosis to be bactericidal in a high enough percentage of cases, it will be a most valuable aid in treating urinary infections. It is indeed gratifying after working many years with the ketogenic diet, first in epilepsy, then in migraines, with none too great a response and without a tremendous percentage of enthusiastic results, to find that my suggestion of its use in urinary infections is meeting with such satisfaction in a new field of application. I think that one point which I observed years ago should be mentioned, namely that approximately 25 to 30 per cent of the women in my early application of the ketogenic diet to epilepsy had a cessation of the menstrual period. There has been experimental work on animals in this country and abroad in the study of the influence on the estrous cycle of a vitamin B deficient diet which produces a cessation of the estrus. The time necessary to use the ketogenic diet in urinary infections is so short that deficiencies are hardly to be considered but this can be compensated by the use of one or more of the various products of vitamin B concentrates that are on the market.

DR HENRY F HELMHOLZ, Rochester, Minn Since Dr Clark and I started working on this subject, it has been largely a matter of a qualitative determination of ketosis, and although we were able to determine that it took ketosis of a certain degree and a p_H of a certain intensity, we did not know until recently what the actual qualities were that were necessary for bactericidal action. I should like to emphasize that ketonuria is bactericidal and not merely bacteriostatic. When ketonuria kills off colon bacilli and staphylococci in six hours, I think it is right to speak of the bactericidal power of such urine. What is the concentration of beta-oxybutyric acid and what is the p_H necessary to produce bactericidal urine? We have been working on that question for some time, and as you possibly saw in a recent publication by Dr Osterberg and me, 0.5 per cent of beta-oxybutyric acid is necessary and a p_H of less than 5.5. The higher the concentration of beta-oxybutyric acid, the greater the bactericidal power of the urine. The lower the p_H , the greater the bactericidal action of the urine. By a rather simple test, which can be made by any one in his office in six minutes a concentration of 0.5 per cent beta-oxybutyric acid can be determined so that it is now a simple thing to know whether conditions are right for bactericidal action of the urine. *Streptococcus faecalis* or *Streptococcus lacticus* is the most difficult one to kill and that *Bacillus coli*, *Bacillus lactis aerogenes* and *Bacillus proteus* are about equally difficult or equally easy to kill. *Bacillus proteus* responds very much more than the other two to a urine of low p_H . In some instances we have found that a normal urine with a p_H of 4.8 will kill, in twenty-four hours, all these organisms, that *Bacillus lactis aerogenes* needs a very much lower p_H , and that it sometimes will grow even at a p_H of 4.6 and 4.5, and that the urine with a low p_H is very much more difficult to produce in the presence of infection due to *Bacillus lactis aerogenes*. Among children, we have found no difference between the ease with which we could kill *Bacillus lactis aerogenes* and *Bacillus coli*. In a number of instances we have been able after six meals on the ketogenic diet to obtain a sterile urine in cases of infec-

¹⁰ Thompson G J The Treatment of Chronic Abscesses of the Prostatic Duct Proc Staff Meet Mayo Clin S 219 220 (April 12) 1933

tions with these organisms. There will be a number of patients who cannot be affected by the ketogenic diet, those in whom the kidney can no longer excrete a urine high in ketones and of low pH . In a recent case in which the blood contained 66 mg of beta-oxybutyric acid per hundred cubic centimeters, we were never able to get a concentration of beta-oxybutyric acid in the urine greater than 0.1 per cent. I think an even simpler mode of securing increased ketosis in the urine will be by feeding beta-oxybutyric acid directly. Unfortunately, at present, it is too expensive to be used in this way.

DR ANSON L. CLARK, Oklahoma City. Dr. Crance is to be congratulated for having pioneered in attacking infections of the urinary tract with dietary measures. I have particularly appreciated his cooperation in confirming the results I have reported. There has been a lot of discussion here today about different bacillary organisms with names that must be confusing to many. Those attempting to apply this simplified treatment will probably do well not to complicate the procedure by trying to classify the organisms. The object of our paper was to simplify the attack on this type of urinary tract infection so as to make it more generally applicable. Highly trained laboratory technicians sometimes have difficulty in classifying the bacteria. Dr. O'Connor has just said that one week his technician will say 'this is an aerogenes bacillus' and a few days later will decide that the organism found in the urine of the same patient is the colon bacillus. The results obtained from this simplified treatment may not be as satisfactory as when one has the assistance of trained dietitians and laboratory technicians. However, this simplified treatment should reach and benefit a greater number of patients.

DR ALBERT M. CRANCE, Geneva, N. Y. I have little to add, except to refer to the remarks of Dr. Helmholz. He made the statement that it was necessary in the aerogenes type to obtain a pH somewhere around 4.5 or 4.4. I have been at this thing good and hard for the past two years, and I think the lowest obtained was 4.7. That is why I can't see why the aerogenes type can be treated by this method.

MODERN STATE HOSPITAL TREATMENT OF THE PSYCHOTIC

AN ATTEMPT AT AN EVALUATION OF PRESENT AND FUTURE TRENDS

CHARLES F. READ, M.D.

AND

JOHN T. NERANCY, M.D.

ELGIN, ILL.

The modern state hospital is a specialized mechanism for the treatment of psychotic patients. A portion of this treatment consists of separation from an environment in which the individual has failed to adjust together with his removal to one which is plastic in its various degrees of simplification to fit reduced powers of adaptation. In this sense the state hospital consists of a series of treatment situations, rather than of structures, and is dynamic, rather than static, the interrelationship of patients, doctors, nurses and attendants being of more importance than the character of the buildings.

Out of years of psychiatric experience, certain desirable physical facilities for the promotion of therapy have evolved, so well standardized as to require no mention here. It is probable that improvement and recovery time diminish in rather direct ratio to any decrease in recognized minimum floor space requirements.

An adequate professional staff carries at least one physician for every 150 patients and includes a patholo-

gist and a psychoanalyst. Provision should be made for interns, together with their proper instruction, and for resident and research associates. Of this, more will be said later. Registered nurses should number at least one for every 100 patients, in addition to the supervising and teaching staff, receiving hospitals, medical and surgical wards, infirmaries, tuberculosis pavilions and special treatment wards, to be staffed by registered nurses and pupils of the training school. The latter should train only high school graduates, and these for registry, with general hospital affiliation as required. Illinois considers it undesirable to train "nurses" who are not eligible for registration. There should be a nurse or attendant for at least every eight patients (on a forty-eight hour week basis, which will soon become universal) with required training courses for all and elective courses for the grade of charge or certified attendant.

The presence of other personnel who are essential to treatment, including dentists, psychologists, psychiatric social workers, occupational therapists, recreational directors and dietitians, is assumed without discussion here.

INFLUENCES ANTIPATHETIC TO INTENSIVE TREATMENT EFFORT

Injected into the hospital situation there are certain antipathetic influences that have their repercussions on patient treatment. Foremost of these destructive tendencies is the disheartening absence of unitary etiology and classic pathologic changes in those psychoses which furnish over a third of first admissions and two thirds of the resident population. Thus ignorance, which should merely challenge scientific curiosity and activity, too frequently furnishes an easy rationalization of their opposites. Pessimistic attitudes of older staff members contaminate newcomers before their insight becomes keen enough to penetrate the various disguises of envy, indolence and incompetence. Lack of team work is pernicious, the blame for it, in hospitals free from political appointees, lies at the door of the superintendent and his first assistants. There are few men who will not gladly work with the group under competent leadership.

Too often the management fails to make liberal time allowances for attendance on scientific meetings and to encourage spontaneous or assigned investigative work in every reasonable way. Few states are definitely committed to a promotional system based on professional merit. State welfare departments do not often bestow an honor, a grant of money for special study or an extended leave of absence with pay for outstanding work. Lack of appreciation retards or stunts the professional growth of many good men who fall just short of being sturdy pioneers. Cooperation between hospitals in the same state is rather uncommon—a situation that is doubtless a vestigial remnant of the days when each hospital, like a feudal barony, was isolated, fearful of outlanders and jealous of interference.

A most important discouraging influence on therapeutic effort arises from a failure to visualize treatment and its results for the benefit of the staff as a whole. Many state hospitals do not keep open books on their various forms of therapy. Physicians too often flounder about in their separate areas of endeavor without accurate knowledge of one another's accomplishment and without even arriving at clearly defined conclusions concerning their own results. We suggest daily journal entries of treatment, posted weekly into

a classified treatment file, from which the results of various types of therapy may rapidly be taken off as occasion requires

SOURCES OF THE THERAPEUTIC DRIVE—THE HEILWILLEN¹ OF THE STAFF AS A UNIT

The professional and personal requirements of staff physicians cannot well be standardized beyond B+ scholarship, adequate internship, professional interest and a well balanced personality, though "plus values" are naturally most desirable. Given this substratum, a man may become a fairly competent, though not an accomplished, psychiatrist in three years—in two if he is an interested, intelligent and well compensated introvert. A judicious admixture of extroverts, with a broad medical and surgical background, is most desirable.

The impetus of an attack on the treatment problem of the psychotic derives primarily from the medical schools and their psychiatric institutes by way of adequate undergraduate and postgraduate training, the affiliation of staff men with the schools as junior faculty members, psychiatric internships and residencies, special training periods for staff men, and the encouragement of research work in the hospitals by graduate students in biochemistry, anthropology, sociology, psychology and psychiatry. Recently Illinois has developed an educational research council, composed of the heads of the departments of neuropsychiatry of the various medical schools, appointed by the governor to advise with him on matters pertaining to the professional work of the state hospitals. The stimulus that such a group may give to therapeutic effort requires no extended comment.

State hospitals must deal with psychotic patients in large groups so far as ordinary care is concerned, but each patient is a person to be studied and prescribed for individually, each represents a summation effect of appalling extent and intricacy. Staff conferences if not thus oriented, become futile diagnostic rituals. We confess that Bleuler's² conception of schizophrenia as "a physical illness with a lingering course" with "a superstructure of psychogenic origin determined by the patient's experiences" carries considerable weight at Elgin. Also we feel that the search for physical determinants of mental disorder is a hopeful, stimulating endeavor. This receptive attitude does not, however, to our mind connote a drive solely in the direction of "detoxication," since we are quite aware of the problems of constitutional inadequacy of the endocrines and of the autonomic nervous system, and welcome psychoanalytic interpretations, along with the possibility of morbid physical reactions to pathologic mental states. We agree with Conn³ that "what we shall do with the facts he [the patient] presents is our major problem and always will be," if by these facts "of the patient's doings and his sayings" we conceive the dynamics of the body-mind organism as a whole. Although major emphasis at present is placed on psychic mechanisms it is still distinctly possible that the exact mental content of a schizophrenic patient may some day assume somewhat the same status as the hallucinations of the alco-

holic addict or the psychic reactions of a patient with dementia paralytica.

Adequate laboratories are obviously indispensable. An autopsy rate of 50 per cent is possible. The effect of frequent autopsies and pathology conferences on diagnosis and treatment is inestimable. A competent pathologist, together with an outspoken psychoanalyst, will keep any staff alive to its responsibilities. Experienced neuropathologists are often difficult to secure, but there should be at least one, with an adequate laboratory staff, available to each state service, together with as many more as possible.

TREATMENT CLASSIC PROCEDURES

Thus far we have briefly stated what we believe to be the principal conditions and circumstances under which treatment may be carried out. We continue with a summary of what may at present be considered the "back log" of accepted state hospital therapy.

1 Perhaps the oldest of all treatments for psychotic patients, if one may call it such, is mechanical restraint. The practical abolition of restraint in the modern state hospital is a very positive contribution to therapy. We find at Elgin that a hospital of 4,300 patients, with a reception service of 150 a month, need carry an average of but one or two patients in restraint daily, principally for surgical reasons. Seldom need a patient be confined in a locked room. Very probably some hospitals do better than this, and others, perhaps, not so well.

2 Psychotherapy is as old as the physician-patient relationship itself. We cannot possibly dissect its ramifications from out the vast mass of contacts which the patient makes with his environment during his hospital sojourn. Its immanence and its directed use have often been commented on. We appreciate the light thrown by psychoanalysis on mental mechanisms, but we do not look to it for the cure of a noticeable percentage of psychotic patients, nor can we accept the proposal that without the use of psychoanalysis there can be no psychotherapy. We believe, as does Schilder,⁴ that "conversation will often substitute for free association methods," and that the community life of the hospital situation, carefully readjusted from time to time by a discerning physician, strengthens the ego system by diminishing the sense of isolation and facilitating a return to reality.

3 As restraint was done away with, occupation emerged, first as a necessity and then as a recognized mode of treatment. Directed occupation now holds a secure place in the therapy of mental disease, almost too secure, in view of the fact that its practice tends to become ritualistic in the absence of thoughtful medical attention. Seldom are there enough well trained aides, and only occasionally a staff physician, sufficiently interested to carry it on properly. There is a tendency to consign patients to this treatment without careful direction and follow up. The time has come to bridge in state hospitals the arbitrary gap between occupational therapy and industrial occupation with a system of promotional employment, combining the two and making use of trained foremen in the key positions of carefully directed industries.

4 Hydrotherapy, ancient in origin, is most useful but too often misused as a form of restraint with therapeutic sanctions. It is easily prescribed, its effects are too seldom studied. We question how many patients

⁴ Schilder P. Principles of Psychotherapy in the Psychoses Psychiat Quart 5: 423 (July) 1931

treated in this fashion are actually benefited by their aqueous contacts per se

5 Only a brave or foolish man would venture to speak ex cathedra of sedation in a state hospital. Unquestionably the reduction of physical restraint and seclusion has increased the demand for chemical restraint. Although hydrotherapy has found its widest application in the excitements, sedation by drugs is often the wiser choice.

6 Exercise, recreation and directed group activities contribute largely to resocialization. Freedom to go and come at will on the hospital grounds strengthens the ego. At least 15 per cent of any ordinary hospital population should enjoy this privilege.

7 The modern state hospital provides physical as well as mental examinations for its patients each six months—something which the medical profession for many years has endeavored to do for the population at large without much success. Surgery does not often remove psychotic symptoms, but the patient who has been well operated on, other things being equal, improves or recovers more rapidly than he or she otherwise would have done. The incidence of tuberculosis in state hospitals necessitates segregation and proper treatment of active cases and the continued observation of quiescent ones. Pretentious units are unnecessary. Repeated roentgen examinations, determinations of blood sedimentation rates at intervals of two months and a three-day clinical observation period every two or three months for a number of years informs us of reactivation in arrested cases. A monthly list of weight losses of the entire hospital population is a distinctive health measure, screening out patients who are failing from whatever cause.

8 Malaria therapy of dementia paralytica has become a classic procedure. Elimination of subjects presenting definite contraindications, repeated blood counts and hemoglobin estimation, together with nonprotein nitrogen determinations, the free administration of dextrose, orally as well as intravenously, and immediate interruption of treatment, when indicated, has held our death rate well below 2 per cent, as the result of this therapy.

9 The state hospital is merely a highly specialized community situation, an integral part of the social group it serves. Out of this conception and its economic implications has arisen a successful effort to follow up patients while they are at home on probation or boarding out on the Gheel plan.⁵ And inevitably as a further development in this direction comes the effort to assist various individuals to make a community adjustment without first requiring of them a course of training and treatment in the hospital situation itself, i. e., commitment. Thus flying squads of psychiatrists, social workers and psychologists, working out from the hospitals, examine problem cases and advise teachers, welfare organizations, judges and physicians concerning their disposition. This is a rational and inevitable undertaking but apt to arouse anxiety and antagonism in the medical profession of some localities.

RECENT AND MORE SPECULATIVE TRENDS

The elimination of evident, together with the search for occult, foci⁶ of infection in the hope of favorably affecting abnormal mental states still beckons us on

despite discouraging reports to the contrary. The large intestine continues to be an object of grave suspicion. We question the alleged demonstration of hepatropic and neurotropic colon bacillus toxins,⁷ yet from time to time we use vaccines prepared from the intestinal flora, with some apparent success. Colonic irrigation, aside from its detoxifying effects, often is markedly sedative. Tonsils, teeth and prostate must be kept constantly in mind, as a search for obscure pathogenesis is made.

Years ago Kraepelin and Wagner-Jauregg considered the psychiatric significance of the ductless glands. Since endocrinology in the treatment of nonpsychotic patients still contends with a baffling constellation of interrelated phenomena, it is not surprising that thyroid therapy, in judiciously selected cases, is the only effective hormone treatment of the psychotic to emerge thus far,⁸ and even here we have not been especially fortunate at Elgin.⁹ The fact that young amenorrheic schizophrenic patients excrete excess amounts of the follicle-stimulating factor, comparable to those excreted by climacteric controls,¹⁰ may have psychiatric significance. Thus far we have been disappointed in pituitary treatment. However, we continue unabashed with endocrine therapy, always hopeful that tomorrow may bring the happy answer.

Prolonged sleep *dauserschlaf*,¹¹ with or without the addition of other so-called nonspecific methods, is a most important therapeutic procedure. Although pioneered nearly fifteen years ago in Europe, it has been reported on infrequently in this country. Unfortunately, the user of this therapy must choose between the Scylla of light sleep with attenuated results and the Charybdis of deep narcosis with better results but occasional fatalities. The technic is exacting, the personnel must be ample and intelligent. The administration of insulin¹² with dextrose to relieve acidosis and the use of coramine as a cardiac and respiratory stimulant have increased the margin of safety.

The quantitative and histochemical deficiency of catalytic iron in the cortical ganglion cells of schizophrenic patients,¹³ plus a direct but temporary stimulation of the nervous mechanism, may explain the fleeting effects of carbon dioxide and oxygen mixture obtained by most reporters.¹⁴ Thus far this effort has not emerged from the research stage. Ours has been the ordinary experience with the barbiturates.¹⁵ Given intravenously they

at times effect an extraordinary rapport with inaccessible patients

"Nonspecific" therapy embraces the use of a vast number of protein and nonprotein substances. Its indications and applications remain purely empirical. Whatever the *modus operandi* may be—pyrexia, somatic protein disintegration, changes in acid base equilibrium, colloidal alterations, activities of reticulo-endothelial cells, mobilization of cholesterol, quickening of metabolism—the conclusion seems possible that there is one common leverage, an action on the autonomic nervous system with an "omnicellular protoplasmatic activation"¹⁶ accompanied possibly by re-inflammation of the originally affected organs. Our best results with fever—and occasionally these are startling—have been secured in the more recent cases. However, we are not enthusiastic and agree with the more conservative statements in the literature (collected reports of 1,795 cases of fever therapy in schizophrenic patients, with 10 per cent of recoveries and 30 per cent of improvements¹⁷).

The electrical cabinet,¹⁸ the electrical heat blanket¹⁹ and similar devices, as well as diathermy²⁰ and radiotherapy,²¹ are valuable in the treatment of dementia paralytica if burns can be avoided. However, we are not convinced that these contrivances are superior to biologically induced fever. The use of typhoid vaccine has received some fresh impetus with the use of the split, or double dosage, method. Negroes, notoriously resistant to malaria, do well with this technic, which produces temperatures well above 106 F. We make free use of a suspension of sulphur in oil, injected intramuscularly.²² A course of from six to eight injections often carries an excited patient along with mild temperature reactions until a course of malaria or other heat therapy can be instituted. Our experience with continuous forced spinal drainage,²³ with and without the use of hypotonic solutions intravenously, has been too small to merit comment. Repeated withdrawals of large amounts of liquor, together with substitution of air, occasionally appears to be useful in the excitement of dementia paralytica as well as in other types of excitement.

State hospital dietaries have in the past been considered principally from the standpoint of weight maintenance. An era of nutritional exploration has now been entered on. The ingestion of inadequate amounts of the vitamins and calcium phosphorus and copper, as well as iron, iodine and the like, may have more to do with mental disease than has heretofore been realized. The experiment—incomplete as yet—of the Otho Sprague Memorial Foundation in feeding 100 young schizophrenic patients at Elgin with a "vitamin

B complex" over a long period of time is a stimulating approach to the treatment of psychotic patients. Previous experiments with animals and school children are interesting.

FUTURE TRENDS

The future of modern state hospital treatment is an interesting field for speculation, especially in view of the past, which presents so many by-paths leading into the swamps of disillusionment. One may question whether any consistent evidence of neuropathology in schizophrenia—against which the effects of therapy may be checked as in dementia paralytica—will issue from laboratories using present day methods of examination. This ground has been painstakingly worked over for years without yielding consistent and generally accepted results. We look more hopefully to the work with living tissues and to those who survey the advances of physiologic chemistry with inspired discernment. Especially does there seem to be some hope in the study of the colloids, the chemistry of films, surfaces and interfaces. Changes in the status of the protein micelles of the blood may reflect correlated changes in the fixed tissues, including those of the brain, possibly an evidence of chronic toxemia, dyscrimism, disturbance of the autonomic nervous system, and the like. We have done some work that contributes slightly to this idea and vaguely indicates tentative therapy along corresponding lines.

We look for the development of an abbreviated psychoanalytic technic applicable to psychotic patients in larger numbers, especially for use during their convalescence before they leave the hospital. And yet, as the tremendous role of the sympathetic and parasympathetic systems is increasingly revealed, we wonder whether, perhaps, we shall not come to know how to balance their activities by other means than psychoanalysis. If, as Hess²⁴ expresses it, "disturbed psychic function can be the expression of disturbed equilibrium between the influences of the parasympathetic and sympathetic principle," very possibly complexes at times become malignant and regressions of personality occur as the result of slowly developing or suddenly acquired autonomic-endocrine imbalance in those who otherwise might have carried on quite well despite certain constitutional inadequacies.

Hoskins' application of Cannon's concept of homeostasis to the research problems of schizophrenia expresses an increasing attention to the reaction patterns of the entire mind-body organism in the study of the psychotic, a direction of thought which should eventually result in a more resourceful, less empirical therapy. The intensive study of a large number of acute cases of schizophrenia in anticipation of their possible recovery, together with a painstaking, retrospective analysis of those who eventually recover, or greatly improve, might reveal important clues to the *modus operandi* of their social readjustment. More painstaking evaluation of such data than have been heretofore attempted would be well worth while, corresponding in psychiatry to antemortem and post-mortem case studies of physical illness.

Increasingly better neuropsychiatric training for undergraduate medical students is to be expected, especially along the line of actual case contacts during clinical clerkships and special internships in psychiatric hospitals. Thus practice, together with residencies in

neurology and psychiatry, plus some training in neuropathology, will furnish staff men prepared to do excellent work if they can be interested in state hospital practice by the allure of proper facilities, housing and recognition of services rendered. We look forward to greater efforts in the future on the part of hospital managements to relieve staff members of unessential work, so that they may devote themselves intensively to their medical task of evaluating the patient-treatment problem. There is a natural tendency to overdevelopment of routine in an effort to stop every possible loophole for public complaint and official criticism.

We deplore the statement that state hospitals deal only with "end products," especially in view of the fact that so much of medical and surgical practice also deals with end results. As psychiatric institutes associated with medical schools increase in number, we hope for programs of teaching, research and treatment that will envisage state hospitals as extensions of these institutes.

We look forward to a state of mind in welfare departments that will seek to encourage the outstanding worker with citations and awards of one kind or another. This idea may even develop so far as to involve the reward of an entire institution with added grants for the continuation of important work on a larger scale. In many commonwealths, partisan politics still impinge unduly on the hospital situation. The wise selection and retention of hospital heads and their assistants a simple measure so obviously right as to require no argument, will doubtless affect the future treatment of institutionalized psychotic patients more favorably than any other one factor in the situation.

When one visualizes the treatment of dementia paralytica as it was prior to the advent of fever therapy and considers the situation today, contemplates the contribution of psychoanalysis to the understanding of the mental phenomena of psychotic states and takes into consideration the tremendous improvement in the entire medical school-state hospital situation during the past twenty-five years, there is good reason to look on the future treatment of psychotic patients as one of the most exciting adventures, as well as one of the most hopeful therapeutic enterprises, in the field of medicine today.

SUMMARY

A modern state hospital is a treatment situation in which personnel is more important than structures.

Various factors, exogenous and endogenous, contribute to the discouragement of therapeutic effort.

The therapeutic drive derives primarily from the attitude of the medical school toward psychiatry.

The orientation of the medical staff toward causation is important. The patient is to be considered as a somatopsychic problem.

Adequate laboratories are as essential to proper treatment as they are in a general hospital.

In addition to classic procedures, more recent trends involve principally the endocrines, various modes of carrying out fever therapy, better nutrition, and various attempts to bring about readjustment of metabolism.

Future trends of therapy will be determined by better training of psychiatrists, together with increased recognition of their efforts, and by further developments of physiologic, especially colloidal, chemistry combined with an increased knowledge of the activities of the autonomic nervous system.

750 South State Street

ABSTRACT OF DISCUSSION

DR. C. O. CHENEY, New York. The authors mentioned one point to which I wish to confine my remarks, and that is the importance of the adequacy and training of the medical personnel. The removal of politics from the appointment of the medical personnel in state hospitals is a fundamental, primary requirement for stability and maintenance of adequate personnel. In New York all the medical positions, as well as others in the state department of mental hygiene, are on a civil service basis, and in twenty-three years experience in the state hospital service I have never known any one to be appointed or removed from a position on account of a political situation. In the department, all medical appointments above the grade of medical intern appointments are made after civil service competitive examinations. Appointments are made after promotion examinations from assistant physician to senior assistant, first assistant and superintendent. A man does not come in as superintendent unless he has come through the various grades in the state department of mental hygiene. Most of the hospitals take on their staffs now only men who have had a general internship because they are approved by the American Medical Association for residencies in psychiatry. The psychiatric institute has continued in its new location as part of the Columbia-Presbyterian Medical Center the practice originated by Adolf Meyer some thirty years ago of having special courses for state hospital physicians. At present it is a ten weeks course given under university auspices by the combined departments of neurology and psychiatry of the medical school at the institute. The head of the department of psychiatry in Columbia is also the director of the institute. The ten weeks course covers both neurology and psychiatry. The course is planned primarily as a source of stimulation for further investigation and study for the men who go back to the hospitals, and we find from experience that this aim is pretty well carried out. Men get points of view that they never have had before or never would be able to get in more or less isolated hospitals. In addition, we have yearly inter hospital conferences. Each year we send out a list of topics to the hospitals for men to work on about a year ahead of the time of the conference. Men from practically all the hospitals worked on problems during the year, and those papers were presented by them at two conferences, one at the institute and one upstate at Utica, twenty-five papers in all being presented. The affiliation with the university is important. The more men who can be brought from surgery and other branches of medicine into state hospitals, the better it is for the hospitals.

DR. GEORGE B. HASSIN, Chicago. The title of the paper by Drs. Read and Nerancy should in my opinion be "Modern Care of the Insane," instead of treatment, for, with few exceptions the treatment of the insane is purely symptomatic, not amenable to medicinal, surgical, psychotherapeutic and even psychoanalytic procedures. This is especially true of the large class of patients classified as dementia praecox, manic depressive, paranoid and similar states. The reason for the poor progress made in the treatment of insanities is the lack of knowledge of pathophysiology. The types of abnormal mental conditions mentioned do not manifest morphologic changes in the nervous system but are most likely caused by some physicochemical and physiologic processes that result in severe toxemia. In some cases, pathologic studies revealed changes in the cerebral subarachnoid space that might be interpreted as a reaction against abnormal chemical substances discharged by a toxic brain into the subarachnoid space. It was considered worth trying to relieve the brain of such abnormal chemical substances by washing them out with diluted physiologic solution of sodium chloride. This has been tried in the Psychiatric Institute of the University of Illinois on four catatonic patients by Drs. Haines and Broder. Intravenous injections of from 1,500 to 2,640 cc. of a diluted (as much as three times) physiologic solution of sodium chloride were given combined with spinal drainage and immediately followed by injections of hypertonic solutions. Though at the beginning the results were somewhat encouraging, in the majority of the cases treated there was hardly any significant change for the better, though the patients stood the treatment well. The method somewhat modified will be tried in cases less advanced and will be described soon by Drs. Haines and Broder.

DR. H. J. GAHAN, Chicago Forty one years ago I entered the state service of Illinois as an assistant physician in the Elgin State Hospital. Dr. Kilbourne, the first superintendent, was granted full control in the construction of the building and the beautiful grounds of the hospital. The front wards were arranged with libraries, billiard rooms, music rooms, private dining rooms and other home comforts. The patients in the back wards were subjected to restraint measures so predominant in those early days. Dr. Arthur Loewy was the superintendent during my early service. His first work was to abolish restraint. We were not favored with the diagnostic knowledge, appliances and procedure so usual today. In 1914 I returned to the service as superintendent of the Elgin State Hospital. The complexion of things had changed because of overcrowding and many of the home features and amusements were necessarily done away with in order to make more room for beds. The building of more units had not been commensurate with the population. Many features for the welfare of the patient during this period were introduced. All restraint measures were removed, and the paraphernalia was either used for better purposes or was destroyed. The removal of bars from the window was carried out and occupational therapy was instituted. There were also more modern methods of diagnosis and treatment, facilitated through the initiation of laboratory procedure.

DR. CHARLES F. READ, Elgin, Ill. Dr. Cheney has spoken from the point of view of New York. There are other states not so enlightened as New York in respect to modern state hospital care. The *Psychiatric Quarterly* represents the work done and reported by the New York State Hospital Service. In many states the hospitals are still quite isolated. They are rather jealous of one another and resent interference from outside, a vestigial remnant of the old days when they were considered more or less as mental barracks. I couldn't quite understand what Dr. Hassin said concerning treatment. I thought I mentioned treatment. Care is not all that can be accomplished in a state hospital. The main purpose of this paper was to present to the section the possibility of a state hospital doing much more for those committed to its custody.

RECOGNITION OF TYPES OF ARTERIO-SCLEROSIS BY OSCILLOMETRY

ALFRED FRIEDLANDER, M.D.
CINCINNATI

The importance of the concept of cardiovascular disease as a clinical entity is fully understood today. Emphasis has been placed, and properly so, on the recognition of cardiac abnormalities of various types. Recently the necessity of obtaining information as to the condition of the vascular tree has begun to be stressed. It is not believed today that arteriosclerosis is merely an expression of aging of the arteries. As Aschoff¹ has said "Arteriosclerosis is not merely a change or transformation attending the process of aging, it is not a mere infirmity of old age, but rather a disease of the vessels manifesting itself mainly during senescence." The clinical recognition of arteriosclerosis thus becomes a matter of import, because the type and the degree of arteriosclerosis present in a given individual have distinct prognostic significance. Any method of clinical examination that gives reliable information as to the condition of the vascular tree thus becomes worthy of attention.

The studies here reported were undertaken as part of the work of the Vascular Disease Clinic of the Cin-

cinnati General Hospital. By means of a new technic, eight oscillometric curves are taken in each instance, and it has been shown that it is the form of the oscillogram, rather than the mere height of the oscillometric index, which is of greatest importance.

METHOD²

The Boukitté modification of the Pachon oscillometer has been used for all determinations. This apparatus has two overlapping, distensible pouches having a combined width of 15 cm. These pouches are enclosed in a rigid web cover fitted with web straps. The apparatus is strapped to the extremity to be studied. By a simple valve arrangement the pouches can be inflated together or singly. A manometric dial permits the recording of oscillometric variations at different pressures.

In each case studied, eight oscillograms are made, i. e. of the forearms, upper arms, legs and thighs on both sides. With the band snugly fitted to the extremity, air is pumped in until the pressure is great enough (in ordinary cases) to prevent any movement of the oscillatory needle. In certain cases even at the pressure of 300 mm. of mercury (the limit of the instrument) oscillations still occur. By means of a needle valve, the pressure is dropped 10 mm. at a time and the height of the oscillation recorded at the various pressures.

Since the time element is a factor, the observer announces the oscillations at the various pressure levels, which are then immediately charted by an assistant. By the use of various chart symbols for the different extremities, the four oscillograms for the upper and again for the lower extremities can be charted on one graph and the two graphs combined on one sheet.

Blood pressure readings are taken by the auscultatory method on the right and left arms as soon as the arm oscillograms are charted. The patient lies recumbent during the test so that the extremities are approximately at the heart level.

With this technic, several hundred charts were made of patients suffering from diverse conditions, material from the medical service of the Cincinnati General Hospital being used. In all cases studied, records were made of the results of physical and laboratory examinations, electrocardiograms and roentgen studies.

As one surveys the rather extensive literature on oscillometry that has appeared recently, one is struck by the fact that in nearly all studies the main emphasis has been placed on the maximal oscillometric phase (MOP), a single arm tracing having been taken.

It is evident now that the form of the oscillogram, taken with the eight tracing technic, is of paramount importance. From the form of the oscillogram certain definite deductions may be drawn as to the condition of the vascular tree. In the consideration of cardiovascular disease, attention ought certainly to be directed to the vascular tree. It would appear that oscillometry affords valuable evidence not only as regards the presence of arteriosclerosis but also as to its type.

The normal oscillogram of the upper arm begins to show an oscillometric rise at about 120 mm. of mercury and drops to zero between 40 and 30 mm. of mercury. Oscillations do occur at higher pressures than 120 mm., but they are not marked. The maximal oscillometric phase occurs between 100 and 80 mm. of mercury. The

¹ Read before the Section on Practice of Medicine at the Eighty-Fifth Annual Session of the American Medical Association, Cleveland, June 14, 1934.

³ Aschoff, Ludwig, in Cowdry, E. V. *Arteriosclerosis*. New York: Macmillan Company, 1933, p. 5.

thigh shows oscillations at higher pressures (around 160 mm of mercury) and the drop occurs around 40 mm. The maximal oscillometric phase occurs somewhat above 100 mm.

In obliterative vascular sclerosis the oscillations occur over a much narrower range of pressure, the maximal oscillometric phase, especially in the lower extremity, is apt to occur at higher pressures—from 140 to 120 mm of mercury—and the height of oscillation is low—from 2 to 3 units.

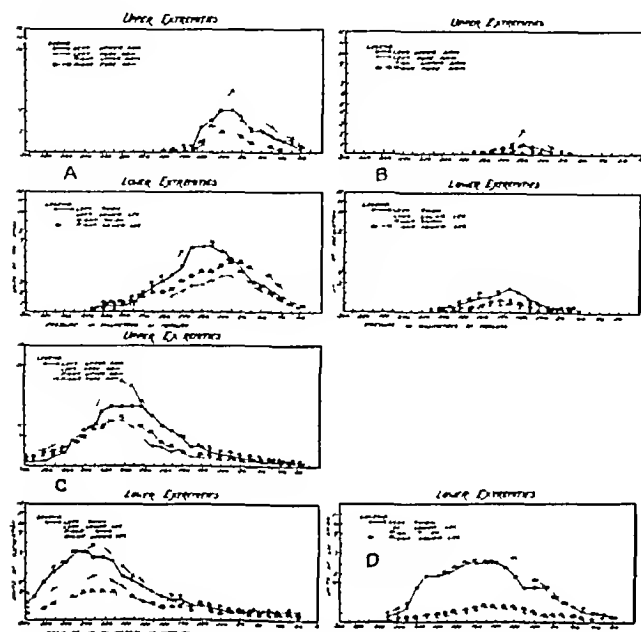

Fig 1—Four typical oscillograms. *A* normal oscillogram white man aged 65 blood pressure 120 systolic 60 diastolic clinical diagnosis pernicious anemia. *B* generalized vascular sclerosis white man aged 49 blood pressure 120 systolic 100 diastolic clinical diagnosis arteriosclerotic heart disease and vascular sclerosis. *C* essential hypertension white woman aged 50 blood pressure 250 systolic 160 diastolic clinical diagnosis essential hypertension and nephrosclerosis. *D* medial arteriosclerosis white woman aged 68 blood pressure 190 systolic 120 diastolic clinical diagnosis arteriosclerosis marked in arteries in lower part of legs.

In hypertensive heart disease with arteriosclerosis, the spread of oscillations is very much greater. The height of the oscillometric index varies very greatly, but the maximal oscillometric phase in both upper and lower extremities always occurs at levels well above 100 mm of mercury.

In malignant hypertension with nephrosclerosis the oscillometric curve is quite characteristic. There is what might be called a definite shift to the left. In both upper and lower extremities the maximal oscillometric phase occurs at levels much above the normal (from 220 to 200 mg of mercury). Oscillations begin at such high pressures as 300 mm of mercury. Furthermore, the oscillations approach zero at much higher levels (around 100 mm of mercury). The unit height of oscillations is high, from 8 to 9 at the maximal oscillometric phase.

In medial arteriosclerosis of the Mönckeberg type, there is marked difference in the curves in legs and thighs, or forearms and arms, or both.

There is a wide spread of oscillations, which begin around 240 mm of mercury, extending to 40 mm of mercury. The maximal oscillometric phase occurs at various pressures and the curve is sometimes of the plateau type.

It must be added that mixed forms of sclerosis are of course common. In such cases, definite diagnosis

cannot be made from the oscillogram alone. The diagnosis of vasospasm of the peripheral arteries can also be made by means of the oscillogram. Where, from the tracing, one suspects that vasospasm exists, vasodilatation is induced by the application of external heat or by the use of other methods of vasodilatation, and the tracing is repeated. The difference in curves thus obtained is striking and, many times, definitive.

With this method, groups of cases of various types have been studied during the past eighteen months to determine the types of arteriosclerosis encountered. A discussion of certain of these groups of cases follows. Figure 1 shows some actual tracings taken.

Bell³ says that medial calcification is one of the most important changes occurring in the muscular arteries. It begins early in life and increases progressively with age but varies greatly in degree in individuals of the same age group. The high relative frequency of medial calcification in the arteries of the lower extremities suggests that functional strain is an important factor in its genesis.

The oscillometric curve of medial sclerosis is so distinctive that the clinical recognition of the existence of the condition is much facilitated. Accordingly, in the analyses of the oscillograms in specific diseases, attention has been given, in each series, to the incidence of medial sclerosis.

Fig 2—Oscillogram in hypertensive heart disease white woman aged 68 blood pressure left 190/110 right 190/120.

HYPERTENSIVE AND ARTERIOSCLEROTIC HEART DISEASE WITH VASCULAR SCLEROSIS

Thirty-six cases of hypertensive heart disease were studied. Ten, or 27.7 per cent, showed medial arteriosclerosis. Four patients were under 40 years of age.

The divergent forms of tracings obtained is well illustrated in figure 2, but it will be noted that the oscillographic criteria for diagnosis are constantly present. The tracing in malignant hypertension with nephrosclerosis (fig 1 *C*) shows its own definite form, well illustrated in the photograph of the tracings made

CORONARY DISEASE

Sixteen patients with coronary disease were studied. Of these sixteen patients, eleven showed definite clinical and electrocardiographic evidence of coronary thrombosis, the other five showed the general picture of coronary sclerosis.

Five of the sixteen cases in the group showed the oscillometric tracing of medial arteriosclerosis. Two of these were cases of thrombosis, the other three of coronary sclerosis.

Fig 3—Oscillogram in rheumatic heart disease white woman aged 22 blood pressure left 145/0 right 145/0

Of the eleven cases in the series in which medial arteriosclerosis was not present, seven showed the picture of general vascular sclerosis in the tracings, four gave normal charts.

The patients with medial arteriosclerosis were all men, ranging in age from 51 to 78.

Of the two patients in the series under 40 years, one was a Negro man with a positive Wassermann reaction and the other a white woman with a negative Wassermann reaction.

At this time in the study it is not possible to draw any definite conclusions from the standpoint of diagnosis or prognosis from the oscillometric curve in cases of disease of the coronary arteries.

RHEUMATIC HEART DISEASE

The relation of rheumatism and various forms of arthritis to arteriosclerosis is still under discussion. MacCallum is not sure that there is a distinct relation. On the other hand, Zeek⁴ analyzed the records of 1,070 autopsies in persons under 30 years of age. Twenty-three cases of rheumatic heart disease came to autopsy. She found that rheumatic heart disease was almost invariably accompanied by atheromatous changes in the aorta, or pulmonary or coronary arteries.

In a second paper she⁵ studied the changes in sixty-two cases of rheumatic heart disease, in persons dying at ages of from 10 to 70. The observations were in accord with those reported in the previous study. In

addition, she notes that lipid deposition has seemed to begin soon after the onset of cardiac disease and that, in a very general way, it has paralleled in degree the cardiac lesion.

We have studied thirty-six cases of rheumatic heart disease. Nine of these (25 per cent) showed the tracings of medial arteriosclerosis, while six of the remaining cases showed vascular sclerosis. Thus of thirty-six cases, fifteen (41.6 per cent) showed the oscillometric curves of arteriosclerosis.

Of the thirty-six patients studied, twenty-three (63.8 per cent) were under 40 years of age. Five (55 per cent) of the nine patients with medial sclerosis were under 40. One of the six patients who had vascular sclerosis was under 40.

The oscillometric curves in rheumatic heart disease present certain well defined characteristics when they show a deviation from the normal.

There is a definite shift to the right. The maximal oscillometric phase occurs at levels usually below 100 mm of pressure in both upper and lower extremities, and there is a high oscillometric index. These observations are not dependent on blood pressure, as will be noted in the tracings shown.

SYPHILITIC HEART DISEASE

In syphilitic heart disease the picture is different. Of fifteen cases studied, fourteen, or 93.3 per cent, showed

Fig 4—Oscillogram in syphilitic heart disease Negro aged 35 blood pressure left 220/70 right 220/70

the tracing of medial sclerosis. All fourteen patients were males, nine white and five Negroes. The high incidence of medial sclerosis in syphilitic heart disease is, of course, well known. By means of the oscillometric curves the clinical diagnosis is much facilitated. As will be seen in the charts, the shift to the right, as found in rheumatic heart disease, does not occur, and the characteristics of the curve of medial sclerosis as previously noted are well shown.

THYROID ADENOMA

Nineteen cases of thyroid adenoma were studied. Two of these (10.5 per cent) showed medial sclerosis, and six of the remainder showed vascular sclerosis.

⁴ Zeek Pearl Am J M Sc 184: 350 (Sept) 1932
⁵ Zeek Pearl Am J M Sc 184: 356 (Sept) 1932

These were all women, aged respectively 29, 37, 40, 41, 46 and 56

Eight of the nineteen cases (42.1 per cent) showed arteriosclerotic curves

At present all cases in which total thyroid ablation is to be done for the relief of myocardial insufficiency are being studied. These studies have not progressed far enough to warrant a report

PULMONARY TUBERCULOSIS

Thirty-two cases of pulmonary tuberculosis were studied at the Hamilton County Tuberculosis San-

Fig. 5—Oscillogram in a case of poisoning with corrosive mercuric chloride marked vasospasm and effect of amyl nitrite. White woman aged 27. blood pressure left 120/80 right 120/80

torium. All were far advanced cases, there were fifteen men and seventeen women. All but four were under 50 years of age. Three of the patients (96 per cent) showed the curves of medial sclerosis, all white men, aged 40, 44 and 53. All three gave a negative Wassermann reaction.

In addition, seven other cases (21.8 per cent) of the group showed the curves of vascular sclerosis, six women and one man, ranging in age from 24 to 35 years. Six of the seven had negative Wassermann reactions, the one positive Wassermann reaction occurred in a white man, aged 28.

The three cases of medial sclerosis showed the characteristic curve in the upper extremity only. This may or may not be coincidence, at any rate, no definite explanation of the finding may be advanced.

The relation of pulmonary tuberculosis to the pathogenesis of arteriosclerosis is still under discussion. MacCallum⁶ is of the opinion concurred in by Ophüls, that tuberculosis has no effect on the arteries, at least so far as arteriosclerosis is concerned.

It is admitted that the series studied is much too small to warrant the making of any very definite statement as to the relation of pulmonary tuberculosis and arteriosclerosis. None the less the observations are sufficiently striking to make further studies advisable.

VASOSPASM

In the routine work of the Vascular Disease Clinic of the Cincinnati General Hospital, the differentiation of vasospasm from obliterative arterial disease of the extremities is an important diagnostic procedure. One method in use is to take tracings of the extremities, blanket the entire body and lay on hot water bottles to relax any existing vasospasm by increasing the environmental temperature, after forty-five minutes of such heating tracings of the same extremities are taken again. This procedure has been used by us on several occasions.

Recently we have become interested in the effect on the peripheral vessels of corrosive mercuric chloride, which produces a definite vasospastic effect. We have taken tracings in our corrosive mercuric chloride (attempted suicide) cases and have temporarily nullified the vasospastic effect by the exhibition of amyl nitrite (fig. 5).

DIABETES

The intimate relation of diabetes and arteriosclerosis is now generally recognized. MacCallum⁷ quotes the studies of Joslin showing that arteriosclerosis is relatively frequent in diabetes, especially arteriosclerosis of the coronaries and of the arteries of the lower extremities. Bell⁸ also comments on the fact that

Fig. 6—Oscillogram in diabetes in a Negro girl aged 13 years. blood pressure left 95/60 right 95/60

diabetes causes a definite increase in the intensity of intimal atherosclerosis. He says that "it is not known whether diabetes has any relation to medial calcification or fibrosis."

We have made tracings in thirty-three cases of diabetes. No attempt has been made to select severe cases. We have taken patients from the outpatient and the inpatient service of the Cincinnati General Hospital. There were fourteen males and nineteen females. The ages ranged from 10 to 79 years, twenty-eight of the patients being under 60 years of age.

Four of the patients, two men, aged 54 and 55, and two women, aged 70 and 71, showed the curve of medial

6 MacCallum W. C. in Cowdry, Arteriosclerosis p. 357

7 MacCallum W. G. in Cowdry, Arteriosclerosis p. 361
8 Bell E. T. in Cowdry, Arteriosclerosis p. 487

sclerosis (12.1 per cent). They were all known to have had diabetes of long standing. The Wassermann reaction was negative in all four.

In addition to these cases, seventeen other patients in the diabetic group showed the oscillographic chart of vascular sclerosis, so that, of the thirty-three cases studied, twenty-one (63.6 per cent) showed evidence of some form of arteriosclerosis.

Of the seventeen patients with vascular sclerosis eleven were under 50 years of age. The figures as given are not excessively high in comparison with other studies. Thus, Joslin showed that in autopsies of 112 persons dying of diabetes the arteries showed advanced arteriosclerotic changes in ninety-four.

What is particularly significant in this small series is that four of the thirty-three cases showed evidence of medial sclerosis. If such a ratio continues to obtain as a greater number of diabetic patients is studied it would seem that one might have to say definitely that medial sclerosis does occur in diabetes.

COMMENT AND CONCLUSIONS

By means of a new technic involving the taking of eight tracings on each patient, oscillograms have been made in a large series of cases. It has become apparent that the form of the oscillographic curve is of importance (a) in determining variations from the normal in the vascular tree, (b) in determining the type of arteriosclerosis existing.

It is possible by this means to make the differentiation between vasospasm and organic arterial disease in peripheral arteries.

One object of these studies was to determine whether the oscillographic records of various types of arteriosclerosis would run true to form. This is apparently true. It is quite possible to make a diagnosis of medial (Mönckeberg) sclerosis by means of this type of oscillogram.

The curve in malignant hypertension with nephrosclerosis is perfectly definite.

The oscillogram in rheumatic heart disease is quite different from that in syphilitic heart disease. In syphilitic heart disease the curve of medial sclerosis predominates.

Even in rheumatic heart disease in young persons a considerable proportion show oscillographic evidence of vascular sclerosis.

The high incidence of arteriosclerosis in diabetes is again demonstrated in these studies. If the present figure of 12 per cent of incidence of medial sclerosis is maintained as the studies progress, an answer will be afforded the question, still moot as to whether medial sclerosis occurs in diabetes.

No definite conclusions as to the existence of coronary thrombosis in suspected cases can be drawn from the oscillogram. Neither can sweeping deductions be made in cases of pulmonary tuberculosis.

But it does seem reasonable in the light of these studies to suggest that, by means of oscillographic studies of the sort here described, definite information may be had as to the condition of the vascular tree.

By means of oscillographic tracings made by this technic, definite information may be had not only as to the existence of vascular sclerosis in a given case but also as to its type.

ABSTRACT OF DISCUSSION

DR CARL J. WIGGERS, Cleveland. Oscillographic methods are based on fundamental physical propositions of dubious validity and are not destined to play any considerable role either in the diagnosis or in the understanding of generalized cardiovascular disease. They have a limited value but are not indispensable in the diagnosis of localized vascular diseases. The amplitude of any individual oscillation is determined by (1) the extra-arterial pressure, (2) the elasticity of the vessel compressed, (3) the height of diastolic blood pressure, (4) the amplitude of the pressure pulse and (5) the speed of the upstroke of the pulse wave, all integrated with the natural frequency of the ponderable swinging lever, which is not sufficiently great to follow pressure changes accurately. To untangle the effects of these numerous factors has proved beyond the capacity of physiologists and physicists up to the present time. I have perused carefully a large volume of French literature but this has not clarified the situation for me. I tended rather to produce a state of complete mental fibrillation. Dr. Friedlander's graphic studies presented here and those which I viewed in his clinic in Cincinnati seem to leave no doubt that if the changes in amplitude of oscillations are plotted in relation to decreasing arterial pressures the plots show striking differences in (a) normal subjects, (b) generalized cardiovascular disease, (c) essential hypertension, and (d) medial arteriosclerosis. As the diagnoses were apparently made preliminary to determining the character of the graphs, it would seem that the method merely supplements the facts on which these diagnoses were based. It would be dangerous to leave the thought that the oscillogram supplies a diagnostic adjunct that in any measure compares with basal metabolism apparatus or the electrocardiograph. Dr. Friedlander should be commended for presenting his facts and for modestly suggesting that they may serve as an adjunct in diagnosis. He deserves special commendation for his wisdom in refraining from explicit interpretations.

DR ALFRED FRIEDLANDER, Cincinnati. Dr. Wiggers is quite right when he says that there are many factors which enter into the interpretation of oscillograms. I agree when he says that he cannot follow the French cardiologists in their conclusions. None the less, admitting that oscillograms must be interpreted in terms of those factors which maintain blood pressure, and likewise admitting the fact that the diagnoses have been made in advance, I still submit that here is a method which if used judiciously, will give definite information as to the condition of the vascular tree. Thus, in the study of diabetes, the relation of arteriosclerosis is becoming more and more important. The relation of coronary disease to diabetes is well known. The management of diabetes per se is often complicated by the presence of cardiovascular lesions. Under such circumstances it becomes a matter of importance to know as much as possible concerning the state of the vascular tree. Continuous studies should add to the sum of our knowledge. Dr. Wiggers came to Cincinnati to address the Heart Institute and saw some of this work. He asked several questions to which I answered "I don't know." He asked "How many cases have you studied?" I said "About 500." Then he replied "Well you have a chance to get somewhere, as any man who has studied 500 cases and doesn't know stands a chance to learn." I propose to keep on trying to learn.

The Sole Function of Milk.—As a matter of fact, milk is the only article of diet whose sole function in nature is to serve as food. Anything else which we eat was "intended" (evolved) by nature for some other purpose and so must not be blamed too severely if it contains something which in too large quantity might not be best for us, or if it falls short of supplying adequately all the things which are essential to our nutrition. We do not seek to avoid every food of which this may be true, but rather to give it its proper place in our dietary or food supply adequately balanced by other foods. What might be treated as problems of slight food injury are thus often more practically treated as problems of nutritional balance.—Sherman, H. C. Food and Health, New York, Macmillan Company, 1934.

CONGENITAL DISLOCATION OF THE HIP

STATISTICAL ANALYSIS

ARTHUR STEINDLER, M D

JACOB KULOWSKI, M D

AND

ERNEST FREUND, M D

IOWA CITY

In the period from 1915 to 1933, 387 cases of congenital dislocation of the hip, representing 501 dislocated hips, have come under our observation. Of this total number, however, only 75 per cent, or 378 hips were treated.

The policy of the clinic in respect to treatment can be shortly stated as follows. The bloodless reduction was accepted as the method of choice within the upper age limits of 5 for bilateral and 6 for unilateral cases, although there were many exceptions which either added to or detracted from the field of indication. External reasons prevented the observance of a lower age limit in the sense that only a few cases were treated in the first and second years of life.

The open operations were adopted not as a competition but as a supplementary method to the closed reduction. It was made contingent universally on failure of the closed method to accomplish reduction or retention of the hip or both. Failure of reduction within the age limit (up to 5 years) was, in our series, not as rare as in other reports (Annovazzi, 6935 cases, 9,660 hips 4.2%, in our series, 7.5 per cent).

The incidence of the primarily irretainable hips, that is, early redislocation, is not as high in our series as is that given by others (Froelich, 20 per cent, in our series, 13.65 per cent).

Both the primarily irreducible and primarily irretainable hip constitute the principal indication for the open method.

The contingent of primarily irreducible hips was increased by our policy of refraining from strenuous and overforceful reduction. The reason for this was not only the immediate danger of applying excessive force but more so the postreduction degenerative changes, such as osteochondritis deformans, coxa plana, osteo-arthritis and other deformities, which are generally considered as results of the reduction trauma. Annovazzi, in 1932, reports definite changes of this type in 32 per cent of the cases. A second point of interest is whether the indication field for open operation can be enlarged by raising the age limit applying to closed reduction.

The palliative operative methods, again, depend for their indications on failure of both closed and open reduction and, principally, on the much wider age limits (to middle age). The average age in the group of palliative methods amounts to 14.2 years. On the other hand, the operative results are naturally so much inferior to those of the age limit methods that there is in this group a high percentage of not treated or conservatively treated cases. Only cases in which there were marked objective and subjective complaints were, as a rule, treated by means of palliative operations.

STANDARDIZATION OF RESULTS

It is difficult to choose from the many suggestions in the literature a proper type of standard both suitable and fair. We have approached our standard as much as possible to that of Galeazzi's clinic (Annovazzi). Clinically good: a stable and painless hip, no easy fatigue, no marked oscillation, good mobility, no limp, no or slight Trendelenburg symptom. X-ray concentric reduction, fair cases with concentric or moderately eccentric placement of the head, but still in the socket, hip stable, only slight limp, no pain or easy fatigue, slight or no shortening, Trendelenburg symptom moderate. Poor: all cases showing pain, bad limp, marked shortening of over 1 inch, and a subluxated or redislocated hip.

THE CLOSED METHODS

Of the cases of bloodless reduction 85 per cent of the patients were females and 15 per cent males. Seventy-one per cent were unilateral and 29 per cent bilateral cases. Associated deformities were found in only 4.64 per cent such as spina bifida, dislocation of the knee, torticollis, clubfoot and coxa vara. A point of interest is the age of the patient at admission while 5 years was considered the upper limit for the closed reduction, 138 children, or 36 per cent, came under observation after 5, only five, or 1.4 per cent, were under 1 year of age.

In the light of experiences on early reduction it would seem that more attention should be paid to public education, which will facilitate admission at an early age.

The great number of patients over 5 are the main reason why in only 249 cases, or 319 hips (64 per cent) bloodless reduction was attempted.

In most of the cases the Paci-Lorenz method was followed and, as a rule, the hip was immobilized in the primary Lorenz position for about three months, then the leg was brought down to Lange's position and immobilized for another three months. Walking exercises were initiated at an average from six to eight months after immobilization. It is the policy of this clinic not to be too orthodox but to fit the maneuver of reduction and the position of immobilization as much as possible to the individual case. If Lange's position seems to be the position of best primary stability, we do not hesitate to put the leg in this position. The casts as a rule, are changed after from six to eight weeks and the position is frequently controlled by roentgenograms. The attempts at reduction varied from one to five, reduction naturally being obtained in most of the cases at the first attempt, more than two attempts were made in only fifteen, more than one attempt was made in fifty-six hips, or 17.5 per cent. After the first attempt, 90 per cent were successful, after more than one attempt, 55 per cent were successful.

Mortality and Morbidity—Immediate mortality was zero, two patients died incidentally shortly after operation. There were eleven postoperative complications: six fractures of the femur, four palsies, of which one was permanent, and one metastatic pyemic joint supuration in a bilateral case.

Table 1 illustrates the postoperative results according to the time of observation.

From one to five attempts were made to secure bloodless reduction. Primary failures of reduction or primary failures of retention (redislocation in the cast) were encountered in forty-three cases, or 13.5 per cent, these

cases were largely reallocated to the group of open operations. The main reason for this group is the relatively high age, twenty-three of these patients, or 53 per cent, being older than 5 years of age.

The frequency of the reduction maneuver necessarily increases the trauma to the hip joint and severe arthritic or degenerative changes may develop. This was seen

TABLE 1—Closed Reduction Operative Results in Congenital Dislocation of the Hip According to Time of Observation

1 Primary failures, hips	62 = 16.00%	(total)	unilateral 28	bilateral 10 (24 hips)
2 Observation time less than 1 yr hips	36 = 11.70%	(discharged)		
3 Observation time 1-5 yrs (av 2.3 yrs)	114 = 26.00%	(total)	unilateral 64	bilateral 20
Results good hips	81 = 70.67%	satisfactory 86%		
fair hips	16 = 14.03%	not satisfactory 14%		
poor hips	17 = 14.91%			
4 Observation time 5-10 yrs (av 6.9 yrs)	71 = 22.00%	(total)	unilateral 37	bilateral 17
Results good hips	72 = 40.00%	satisfactory 73%		
fair hips	20 = 27.57%	not satisfactory 27%		
poor hips	19 = 20.70%			
5 Observation time 10-20 yrs (av 14 yrs)	46 = 14.40%	(total)	unilateral 26	bilateral 10 (20 hips)
Results good hips	24 = 52.17%	satisfactory 70%		
fair hips	6 = 17.39%	not satisfactory 30%		
poor hips	14 = 30.43%			

especially if the closed reduction method was tried more than once in children over 4. In these, one attempt should be sufficient.

In thirty-six the postoperative observation period was either less than one year or they were still in the cast, so that the result could not be judged, or they could not be followed up at the end of the immobilization period, these cases were eliminated from the group. The remaining 231 hips are divided into three groups, with observation from one to five, from five to ten, and from ten to twenty. The classification of these results was on the clinical evidence rather than on the roentgenograms, the latter often showing considerable changes of the femoral head and acetabulum in cases with good or very good results.

It will be seen that the incidence of satisfactory results (good and fair), at one to five years observation, is 85 per cent against 15 per cent unsatisfactory.

In the second group, with the observation time from five to ten years, satisfactory results are noted in 73 per cent and unsatisfactory results in 27 per cent.

In the third, with the observation period from ten to twenty years, satisfactory results were obtained in 70 per cent and unsatisfactory results in 30 per cent.

One notices the rapid decrease of the good results as the period of observation extends, and about 25 per cent of the good results become fair or poor beyond five years of observation. If it is considered that the average observation time for the last group (from ten to twenty years) is fourteen years, and the average age at reduction about 3, the patient at the end of observation is still in the growing age, and the definite outlook of the bloodless reduction is not as good as some clinical statistics might imply. For this reason it may be safe to say that statistics of closed reduction of the hip are of only relative value as long as they do not report on a good number of cases observed for a certain period after bone growth has stopped.

A painless and stable hip ten years after reduction is not an absolutely definite criterion, and some of the older cases (fifteen years) of congenital dislocation of one or both hips, which have never been treated, may show a painless and stable hip.

Table 2 shows the operative end results arranged according to age groups.

Group A, patients from 1 to 2 years old at the time of reduction, twenty-six hips, or 82 per cent. Satisfactory results (good plus fair) were obtained in 54 per cent, unsatisfactory in 38 per cent, and undetermined 8 per cent.

One notices the low percentage (82) of closed reductions attempted before the second year of life, and in the small number of cases in which closed reduction was done at this age the results were not as good as expected, being only somewhat over 50 per cent. This seems to be in contradiction to the more recent reports on the exceptionally good results of early treatment of congenital dislocation of the hip. However, it is probably due to the fact that the cast treatment which was applied was not the best treatment for early childhood, as it is difficult to maintain the position in a well fitting cast in a very young child.

Group B, patients from 2 to 3 years of age at the time of reduction, 103 hips, or 30.28 per cent, sixty-nine unilateral and thirty-four bilateral. Satisfactory results were obtained in 68 per cent, unsatisfactory in 20 per cent, and undetermined in 12 per cent of the cases.

Group C, patients from 3 to 4 years old at the time of reduction, eighty-six hips, or 27 per cent, forty-two

undetermined	4 = 5.71%		

unilateral and twenty-two bilateral. Satisfactory results were obtained in 57 per cent, unsatisfactory in 30 per cent, and undetermined in 13 per cent.

Group D, patients from 4 to 5 years of age at the time of reduction, thirty-two hips, or 10 per cent, sixteen unilateral and eight bilateral. Satisfactory results were obtained in 53 per cent, unsatisfactory in 38 per cent, and undetermined in 9 per cent.

Finally, group E, patients over 5 years of age at the time of reduction, seventy hips, or 22 per cent, thirty-

eight unilateral and sixteen bilateral. Satisfactory results were obtained in 43 per cent, unsatisfactory in 52 per cent, and doubtful in 5 per cent.

Comparing the results in the unilateral and bilateral cases in all age groups arranged according to periods of postoperative observation, one finds a considerably higher percentage of satisfactory results in the unilateral cases, giving the prognosis in bilateral cases in our series throughout at about 10 to 20 per cent worse than in the unilateral cases. As there is no essential difference between the unilaterally and bilaterally dislocated

Note. Anteversion was common but cannot be numerically recorded owing to inaccuracy of the observation.

hip so far as the reduction maneuver is concerned, the difference can only lie in the greater difficulty in retaining the two reduced hips by a plaster cast. We would consider the numerical difference between the satisfactory results seen in bilateral cases as purely and primarily due to technical insufficiency.

Redislocation of the hip occurred in sixty-six cases altogether, or 26.5 per cent, but in thirty-four of these (13.64 per cent) the redislocation was noticed within the immobilization period.

In thirty-two cases the redislocation occurred more or less after the end of the immobilization period, in one case fifteen years afterward, following a direct trauma to the hip joint. Besides the interposition of the soft tissues, the main reasons for the late redislocations are the shallow acetabulum and the development of deformities of the upper end of the femur, leading sometimes to complete absorption of the epiphysis, to subluxation and finally to complete dislocation of the upper end of the femur.

THE OPEN REDUCTION

The open reduction was done in thirty-eight cases with forty-four hips, 7.89 per cent males and 92.11 per cent females. Twenty-four, or 63.18 per cent, were unilateral, and fourteen, or 36.82 per cent bilateral. The age limits varied from 21 months to 11 years, the average age being 4.84 years.

The indications for open reduction were failure of reduction in twenty-two and failure of retention in fifteen cases, primary open reduction was undertaken in only seven cases.

Preoperative treatment consisted in preliminary skeletal traction, which, however, was effective in only fourteen out of twenty-two cases. The interval between the attempted closed reduction and the open operation was on the average forty-nine weeks.

Table 3 analyzes the anatomic difficulties in open reduction. Capsular obstacles are in the foreground,

particularly the iliac adhesions (twenty-one hips) and the hour-glass constriction (twenty-two hips). Of the muscular obstacles the adductor contraction is the most important, of the skeletal, the plugging of the acetabulum by soft tissue and the ligamentum teres (twenty-two and eighteen hips, respectively). Cartilage changes were noticed in ten, deformities of the head in seventeen cases.

In the technique of the operative reduction, Smith Petersen's approach was used in forty out of forty-four cases and Whitman's approach four times. In addition to the open reduction, shelving was carried out in ten cases.

Postoperative treatment consisted in the plaster immobilization for a duration of from seven weeks to five and one-half months, on an average of 10.33 weeks, either in Lange's position (65.78 per cent) or in the primary Lorenz position (34.22 per cent).

Physical therapy followed the cast treatment in twenty-six cases or 68.68 per cent, for an average of 4.7 weeks. Weight bearing is allowed one month after the plaster has been removed.

Secondary procedures were necessary in eighteen cases, consisting in manipulation, osteotomies (subtrochanteric, supracondylar), the setting down of the trochanter, or a Soutter operation. In one case drainage had to be instituted because of suppuration.

The immediate operative results are shown in table 4, primary open reduction was successful in thirty-eight and failed in six hips.

There was primary redislocation in two (reoperation successfully done in one) and primary subluxation in four hips.

TABLE 4—General Operative Results

1 Reduction	
Primary open reduction successful in	38 (63.6%)
Open reduction failed in	6 (23.64%)
(one responded and failed again)	
2 Retention	
Primary redislocation (one reoperative success)	2 (5.26%)
Primary subluxation	4 (10.52%)
3 Complications	
(a) Mortality	1 (2.63%)
(b) Pneumonia	2 (one death as above)
(c) Infection	1
(d) Ray changes	Total hip roentgenograms studied 26
Changes occurred in 13 (46.42%)	
Neck	0
{ coxa vara	4
{ thickening	1
{ flattening	1
Head	3
{ dissolution	2
{ roughening	2
{ slight slipping	2

The postoperative mortality consisted of one case (2.65 per cent) from pneumonia, the morbidity, two cases from pneumonia and infection.

The roentgenographic changes observed secondarily following the first attempt by the open reduction were studied in twenty-eight cases and were found to be present in 46.42 per cent. They consisted in coxa vara, coxa plana, absorption and epiphyseal slipping.

Table 5 gives the analysis of operative end results. The report covers twenty-seven cases, or thirty hips. The general average of good and fair results was 70 per cent, and of poor results 30 per cent. At ages up to 6 years sixteen are found satisfactory to four unsatisfactory (75 and 25 per cent). At ages of 6 years or over are found five satisfactory and five poor results, or a ratio of 50/50 per cent.

The unilateral cases show a decided advantage over the bilateral, namely fourteen satisfactory to three unsatisfactory results, or 84.16 per cent, against the bilateral cases in which operation was performed on both or on either one side with a ratio of 7.6 seven satisfactory to six unsatisfactory hips, or 55.45 per cent.

THE PALLIATIVE METHODS

The indication is conditional both on the actual or probable failure of the closed and the open reduction in older individuals. Of the operations advocated and

practiced, the osteoplastic shelf reconstruction is in the foreground. Answers to our questionnaires combining the statistics of Drs. Le Breton, Stern, Conn, H. R. Thomas, McAusland and Miller aggregate sixty-nine hips with fifty-four satisfactory and fifteen unsatisfactory results, or 78.22 per cent. Next to this the osteotomies (Schanz and von Baeyer-Lorenz) are considered valuable. Zahradnick reports twenty-one good results among thirty cases of Lorenz bifurcation observed over two years or more, and Hass reported favorably on twenty bifurcation operations. Answers to our questionnaires gave the combined statistics of Drs. Conn, Le Breton, Stern and Gaenslen as twenty-five hips with twenty-one satisfactory, two unsatisfactory results and two undetermined, a proportion of satisfactory results of 91 per cent.

Among the older methods, the transposition is uncertain and unreliable, arthrodesis is an operation favored by British surgeons.

Our material of the palliative treatment comprises fifty-five cases, of which forty-six were treated, twenty-five operatively, comprising thirty-one hips and twenty conservatively, or twenty-three hips, ten cases were not treated.

Objective indications included irreducibility and failure of retention, or redislocation, age and degree of dislocation, bad limp or positive Trendelenburg symptom. The subjective indications added to the objective mentioned were pain, fatigue and spasm. Of the four patients with objective symptoms alone, nine were shelved, and one had adductor tenotomy. Of the thirty-one patients with subjective as well as objective symptoms, eleven had shelving, three were osteotomized, and two had adductor tenotomy.

Relation of the amount of shortening to the age of the patient was found as follows. Seventy-five per

cent of 1 inch of shortening, 52 per cent of 1 to 2 inches of shortening, 88 per cent of 2 to 3 inches of shortening and 100 per cent of more than 3 inches of shortening were 12 years or over.

Table 6 gives the preoperative and postoperative roentgen observations. We found, preoperatively, absorption of head and neck (two cases), the secondary flat acetabulum with small primary socket (twenty-six cases), subluxation (two cases), nearthrosis (one case), postoperatively the shelf was absorbed in five cases, the shelf was preserved in eleven cases, and chocking was not done in four cases.

Table 7 gives the analysis of palliative operations.

1 The end results of the shelving operation according to the time of observation, age and shortening, gave a percentage of satisfactory results of 84.2.

2 This series is too small to be of much statistical value for osteotomy and tenotomies. Four osteotomies (Schanz and Lorenz) gave uniformly satisfactory results, as did also four adductor and flexor tenotomies.

In comparing the intracapsular and extracapsular shelf technic in respect to subsequent mobility of the hip, we found that there was no disadvantage in the intracapsular shelving which was carried out in the majority of the cases (15.5).

The conservative treatment was carried out in a number of cases which, because of age, shortening or

TABLE 6—Preoperative and Postoperative Roentgen Observations in Congenital Dislocation of the Hip

lack of subjective complaints did not seem to be proper material for operation. It was found not without value in a number of cases, particularly the extension shoe and the securing of the pelvis by belt or brace. Of twenty cases so treated, three were followed up for a sufficient length of time, only four failed to show any relief whatever from the mechanical appliances, and in nine the gait was improved and the subjective symptoms relieved.

CONCLUSIONS

1 Summarizing, we can say that the extreme optimism concerning results in the closed method, as it is shown by some German and Italian authors, does not seem to be entirely justified. Results become definitely worse with the duration of the observation period. A systematic after-care and long lasting follow up of

the patients is absolutely necessary (roentgenograms should be taken at least twice a year in the first five years after reduction, and at least once a year in the following years) Results of definite significance are given only by patients who, after reduction in childhood, are grown up to manhood and womanhood. These cases will settle the question of functional disability, especially if compared with the nontreated cases of the same age group. Considering the great change which the treatment of congenital dislocation of the hip has undergone since it was initiated by Paci and Lorenz, one must say that the definite proof of the value of the method, expressed in percentages, cannot yet be given. We do not doubt, however, that with the greater precautions in the after-treatment and the perfection of orthopedic means, the cases which come to reduction today have by far a better outlook than those in which reduction was done from ten to fifteen years ago.

2 As open reduction was practiced not as a competitive but as a supplementary method to closed reductions, it must be judged on its own merits and not by

anatomic point of view the standard for this type of operation is naturally lower than that for the reductions. Functionally, however, available statistics show an encouraging percentage of acceptable results both for shelf operations and for osteotomies.

ABSTRACT OF DISCUSSION

DR JOSEPH A. FREIBERG, Cincinnati. The authors have covered the entire field of treatment of congenital dislocation of the hip, both conservative and surgical treatment has been discussed in a thorough manner and concise data have been given. After a study of 500 cases Dr Steindler and his co-workers conclude that a preliminary closed reduction should be attempted within certain age limits. I am entirely in accord with this conclusion. I would stress the importance of early recognition of congenital dislocation of the hip. The earlier it is recognized, the simpler is the treatment. This is a problem of propaganda to the general practitioner rather than to the orthopedic surgeon. The authors do not emphasize sufficiently the importance of palliative operative treatment of congenital dislocation of the hip in the older child. It is their opinion and mine also that palliative operative treatment is preferable to open reduction with the possibility of a resulting stiff hip in the older child.

Standard—Good walking well free motion good endurance fair walking better less limp more endurance poor no better essentially no increase of endurance

comparison with the bloodless results. We have tried to keep separate the two fields of indication. Its proper province is the irreducible and irretainable case within the bloodless age limit.

Outside this limit, it does not very materially enlarge the territory of reducible cases, even though our age range was up to 11 years. The fact that beyond 5 years of age the satisfactory result rapidly decreased would indicate that the upper age limit for open reduction in general would be about 8 years. This agrees with Dickson, who recommends open reduction for all patients between 4 and 9.

3 The significance of the palliative methods lies in its preventive effects on the increased functional difficulties during and beyond puberty and on the late sequelae seen in unreduced dislocated hips in middle age, the secondary arthritis due to the static insufficiency.

It seems to us that from this point of view the simple operations, namely, the shelving and the osteotomy, will undoubtedly gain in favor because of the lesser danger of operative failure and of postoperative complications. To date we have no statistics and late end results of palliative operations. In view of the increasing evidence of late degenerative sequelae of the unstable, unreduced hip, it may be assumed that the future will find the indication field of the palliative operation extended rather than restricted. From the

DR SAMUEL L. ROBBINS, Cleveland. The important conclusion can be drawn from this paper that the cure of a dislocated hip is unfortunately not a reality. Without doubt there persist anatomic imperfections but here as in other congenital malformations, it is not possible to make perfect organs out of imperfect elements. Not all is finished when a dislocated hip has been replaced. The construction of the hip is a complex work, which must be observed for a long while, especially at the age of puberty, in order to preserve good results which are unhappily the exception. A girl, aged 13 years, who had bilateral dislocation of the hip replaced at the age of 2, had no pain whatever from the age of 3, no limp and no trouble. Three weeks before the examination the patient complained of severe pain and instability on the left side. She was well developed and walked about favoring the left side. On reclining, there was no asymmetry noted, except atrophy of 1½ inches on the right side. There was no shortening, and motions on the good side were normal in all directions, on the left side they were limited only at the extremes of motion. Roentgenograms demonstrated the neck to be short and squatty on the good side, the head was mushroomed, and the roof of the acetabulum was oblique. On the ill side the head and neck were well shaped, and there was only a slight obliquity of the roof of the acetabulum. First it was thought that the markers on the x-ray plate were not correct and exposures were taken. On careful examination of the left side atrophy of the head of the femur and also of the roof of the acetabulum was found. Because of pain, the child was put in a hip spica, which she wore for eight weeks. After four months, she was able to get along without any pain or limp. Roentgenograms of the left hip showed no atrophy. She has been perfectly well.

I believe that this condition, if overlooked or if neglected, would have resulted in a possible redislocation or of a fragmentation of the head

DR. ARTHUR STEINDLER, Iowa City Allow me to say that the greater credit belongs to my associates, Dr Kulowski and Dr Freund I thank Dr Freiberg for calling attention to the necessity of early recognition and also for taking the stand that he will refrain from attempting the reduction after a certain age limit is reached and content himself with the palliative operations I also want to thank Dr Robbins for pointing out again that long-range observations are absolutely necessary

Clinical Notes, Suggestions and New Instruments

A METHOD OF ARTIFICIAL RESPIRATION ESPECIALLY USEFUL FOR THE PARALYZED PATIENT

T. C. THOMPSON, M.D., NEW YORK

Fellow in Orthopedic Surgery Hospital for Ruptured and Crippled

The advent of the Drinker respirator has made possible the prolonged treatment of respiratory paralysis, but the problem still remains of treating the patient until he can be placed in a respirator. Many large institutions keep a respirator always on hand for such emergencies, but it is obviously impossible for the family doctor or smaller hospitals to have one immediately available and some means of artificial respiration must be resorted to. Numerous methods have been described and it is only because in my experience they have at times been unsatisfactory that the following modification is suggested. The older standard methods have been compared¹ and the only one found adequate was the Schafer prone pressure method. This will maintain normal exchange in the ordinary case and is fairly satisfactory except that the repeated pressure on the lower thorax often causes considerable soreness. Most authorities agree that the Schafer method is to be preferred to any type of mechanical device such as the pulmotor or lung motor, and it is the accepted standard method of the American Red Cross Life Saving Corps.

The following illustrates the type of case in which the existing means of artificial respiration with the exception of the Drinker respirator are unsatisfactory and explains how this method was developed.

REPORT OF CASE

A youth aged 18, was admitted on the fourth day of his illness. He had almost complete paralysis of both lower extremities and abdomen with urinary retention. The arms and neck were moderately affected but respiratory movements were quite good. He was very sensitive to pressure over the entire trunk and extremities. A lumbar puncture was done and the diagnosis of anterior poliomyelitis established. Because the paralysis seemed to be progressing and his temperature ranged from 100 to 102 he was given convalescent serum intraspinally, intravenously and intramuscularly. Two days later he complained of a "tight feeling" in his chest and felt that he could not take as deep a breath as he wished. The excursion of his chest seemed unchanged, his color was good, and he seemed to have good power and control in his thoracic muscles. On the next day at 5 a. m., after a fairly comfortable night, his respirations became slow and shallow. He became cyanotic and in a few minutes lost consciousness. He was given stimulating drugs with some temporary improvement, but he remained slightly cyanotic and respirations were slow and shallow. Respirations became steadily slower until about 7:30, when they practically stopped. The patient was deeply cyanotic and about two or three jerking gasps were produced by the neck muscles each minute. When his pulse began to fail, it was thought that the end was near. He was taken out of his plaster bed placed on the floor and artificial respiration by the Schafer prone pressure method was begun. By the use of considerable force a moderate exchange could be obtained. By 8:30 the patient's condition was considerably better, though

he was still unconscious and moderately cyanotic. Strong pressure on the lower part of the thorax caused a slight respiration but the patient was so extensively paralyzed that the chest remained practically in a position of expiration and there was no gasping inspiration like that which usually occurs in a subject who has a normal resilient thorax. Several other methods of artificial respiration were attempted without avail. No method seemed to cause the patient to inspire.

While various maneuvers were being tried it was found that, if the patient's pelvis was lifted upward about 18 inches from the floor by a hand under each anterior superior spine the back sagged into marked lordosis and a deep gasping inspiration could be heard. This was almost surely produced by the sagging of the abdominal contents in the position of lordosis, causing descent of the diaphragm and consequently a moderately deep inspiration. When the pelvis was released, a long expiration could be heard as the relaxed abdomen came in contact with the floor. An additional pressure on the lower ribs posteriorly after this caused a small additional expiration. Each time this maneuver was repeated the patient's color visibly improved and by 10 a. m. his pulse was strong, his lips were red and he was semiconscious and able to take water and to complain bitterly of his soreness. A respirator could not be

TABLE 1—Exchange Per Minute (Cubic Centimeters)

Subject	Vital Capacity	Average Normal Minute Volume	Exchange per Minute			
			Schafer Method	Lifting by 1 Man	Lifting by 2 Nurses	Combined Lifting and Schafer Method

TABLE 2—Exchange Per Respiration (Cubic Centimeters)

Subject	Vital Capacity	Average Exchange per Normal Respiration	Exchange per Respiration			
			Schafer Method	Lifting by 1 Man	Lifting by 2 Nurses	Combined Lifting and Schafer Method
S	4,715	622	1,194	1,432	1,156	3,125
T	5,600	665	906	2,010	1,896	3,574
G	2,790	262	961	1,006	1,349	1,121
B	2,200	272	1,069	1,188	1,091	2,044

obtained before 5 p. m., and for eight hours all types of artificial respiration were attempted. Even with extreme pressure a good color could not be maintained by the Schafer method, but by lifting the patient by the pelvis almost to the knee chest position and then allowing him to flatten out on his abdomen on the hard floor, sufficient exchange could be maintained even though this was done as few as five or six times per minute. As the patient complained of any pressure on the thorax, the Schafer maneuver was omitted.

The patient's general condition improved greatly in the respirator. He was rational within a few hours, but it was three weeks before he made the slightest attempt at voluntary respiration when he was removed from the respirator for periods of one or two minutes at a time for nursing care. At the end of six weeks he could remain out of the respirator indefinitely, but daily periods in it were continued until the patient's vital capacity exceeded 2,000 cc., about one year later.

This experience over a period of eight or ten hours with an almost completely paralyzed subject led me to try this new method on several patients who stopped breathing during the administration of an anesthetic. It was found to be as efficacious as the Schafer method and no more difficult except when the subject was very heavy. It can be done practically as well by two people lifting the pelvis of the subject by the two ends of a folded towel placed under the subject at the level of the groins.

Comparison of the respiratory exchange obtained in normal individuals by different artificial methods is not entirely satisfactory because of the fact that the subject either resists or assists the operator, and any increase in respiratory exchange

above the body requirements will cause inhibition and a decrease will cause an increase in voluntary movements. In spite of this fact measurements of respiratory exchange in normal subjects obtained by several methods were made and the results are shown in the accompanying tables. A slow rate was used to avoid overventilation, and each method was used only for a period of one minute. Long periods of rest were given between tests to allow the subject to attain normal exchange again. In each instance the exchange obtained by lifting the patient by the pelvis exceeded that obtained by the Schafer method. Combining this procedure with the Schafer method produced an exchange with each respiration which was more than one half of the vital capacity of the subject.

The Schafer method depends on compression of the lower part of the thorax to produce expiration while the method

Fig 1—Position of patient

described here is directed toward producing adequate descent of the diaphragm and consequently a deep inspiration. The two methods together insure an exchange far exceeding that obtained by either one alone.

DETAILS OF THE METHOD²

1 The subject is placed in the prone position on a hard surface as in the Schafer method. It is well to place a folded coat or small pillow beneath the clavicles and upper part of the chest (fig 1).

2 While sitting on a low chair or kneeling the operator puts one hand beneath each anterior superior spine and lifts the pelvis well off the ground so that the back arches and the abdomen sags downward (fig 2).

Fig 2—Procedure by operator

3 The operator lowers the subject to the floor slowly to his original position. If maximum exchange is desired the usual Schafer procedure of pressing downward and forward and compressing the chest over the lower ribs is then carried out.

4 This procedure is repeated from six to ten times per minute.

CONCLUSIONS

1 Respiratory failure with extensive flaccid paralysis of the trunk muscles cannot be treated satisfactorily by the Schafer method of artificial respiration.

2 Lifting the pelvis of a subject in the prone position and allowing it to fall back to the floor produces adequate respiratory exchange even in the paralyzed subject.

3 This procedure, combined with the Schafer prone pressure method, produces a remarkably large respiratory exchange.

321 East Forty-Second Street.

² Mr. G. R. Gardlestone, F.R.C.S. of Oxford, England, made suggestions that led to the use of this method on the patient who was so extensively paralyzed.

SECONDARY ANEMIA COMPLICATED BY AN EXTRADURAL ENDOTHELIOMA OF THE THORACIC SPINAL CORD

EXHIBITING AN UNDESCRIBED PHYSICAL SIGN

FREDERICK R. TAYLOR, M.D., AND W. K. McCAIN, M.D.,
HIGH POINT, N. C.

Cord symptoms due to pernicious anemia, or even to severe grades of secondary anemia, are frequent enough to need no special discussion. In the case about to be described, however, the combination of a moderately severe secondary anemia with spinal cord symptoms suggestive in character, but not in distribution of those occurring in pernicious anemia, the cord symptoms being due to a nonmalignant extradural tumor, seems sufficiently unusual to warrant description, the more so, perhaps, because a physical sign was discovered by one of us (F. R. T.) by accident that has, so far as we know, not been described before.

Mrs. W. C. C., aged 23, an electrician's wife, came to one of us (W. K. McC.) complaining of difficulty in walking. It was obvious from a preliminary examination that she suffered from an organic neurologic condition, and she was referred to the senior author for further study. Her history was taken on Jan. 27, 1934, and its essential points are as follows:

For the past year she had noticed some difficulty in walking in a straight line. Until recently there had been no real staggering but merely a difficulty in holding her course. She would tend to zigzag, because she was constantly having to correct her direction of progress. She is sure there was no constant deviation to one side only, as she would often bump into either the right or the left side of a doorway while attempting to walk through it. This difficulty did not seem to be due to any visual disturbance. She thought little of it at the time, though it persisted without any new symptoms until about a month before examination. Then she noticed a tickling sensation in the front of both knees, worse in the right as if insects were crawling over her skin. This lasted about two weeks. Then followed a numbness in both legs from her knees down, worse in the toes and on the right. This had spread upward, till she was numb to some degree up to the waist. During the past two weeks she had felt as if her feet were "asleep" and had had severe difficulty in walking, which condition was rapidly getting worse. She staggered badly, and her leg and thigh muscles felt stiff to her. She had had no pain at all other than occasional inconstant slight backache, no worse or different than she had often had most of her life. She had noticed no trouble with her arms or hands and could write or sew as well as ever. However, one of us (W. K. McC.) thought he noted a little clumsiness in her hands as she started to unfasten her dress. She had had no dizziness or tinnitus. Her appetite and digestion were normal. There was a certain degree of constipation but she took no laxatives other than very rarely a dose of salts. She had no difficulty in controlling the bowels or bladder. Her feet felt swollen to her but did not look so, she said. Her backache was lumbosacral and appeared to be associated with the menstrual periods. It was never severe. There were no abnormal urinary symptoms. The periods were regular, every four weeks, and lasted a week, the flow was free, but no more so recently than always, there were no clots, and she did not suffer much with them. There was no suggestion of any acute infection at the onset of the present trouble. Her husband stated that she formerly had an excellent color but recently had been getting very pale, with a somewhat yellowish hue to her skin.

Her past history, habits and family history threw no light on the case.

The patient was 5 feet 2 3/4 inches (156 cm.) high and weighed 111 3/4 pounds (51 Kg.). The temperature was 98.4 F. The pulse was 88 and of normal rhythm and quality. Respirations 22. The blood pressure was 120 systolic, 70 diastolic. The patient was rather strikingly pale, with a slightly yellowish hue. This was hardly the typical lemon yellow of an advanced pernicious anemia. The mucosae as well as the skin, showed this pallor. There was no jaundice. Her gait was grossly affected, being of a spastic-ataxic type. She could not stand without support though she did not show the wide preliminary swaying of the usual marked Romberg sign. She simply fell at

once unless supported. This occurred with the eyes open or shut. Vision was 20/30 in both eyes, with some astigmatism, apparently normal, except for a refractive error. The eye-grounds were normal. The cranial nerves were normal. The head, neck and chest showed no abnormalities other than the pallor. The spine showed no tenderness or bulging, but examination disclosed a sign, apparently a reflex, hitherto unknown to us viz, percussion over the lumbar spine caused a contraction of the adductor muscles of both thighs. With the patient sitting up, this produced a sudden momentary compression of the knees together. The patient herself noticed this, and the result was quite constant when percussion was done over the lumbar vertebrae, but the reaction did not occur when percussion was done over the thoracic or sacral region. There were no neurologic changes above the waist line at this time. The abdomen showed no evidence of visceral disease. Pelvic examination by one of us (W. K. McC.) was negative except for the fact that it was difficult to make, owing to marked adductor spasm of the thighs.

The patellar reflexes were exaggerated to an extreme degree, ankle clonus was marked on the left doubtful on the right. The Babinski reflex was positive on both sides. There was hypesthesia for touch anteriorly from the level of the umbilicus to the ends of the toes, and for pain and temperature from the middle of the thighs anteriorly down. Posteriorly, sensation appeared to be normal. In other words, the lumbar root distribution was affected on both sides the sacral on neither. The symmetry of the involvement was quite remarkable. The sense of position seemed normal.

The urine was normal. Blood examination revealed hemoglobin, 55 per cent, red blood cells 3,500,000 white blood cells not counted, polymorphonuclears, 67 per cent, lymphocytes, 25 per cent, large mononuclears, 5 per cent transitionals, 2 per cent, eosinophils, 0, basophils 0. No blasts were found, but marked anisocytosis and poikilocytosis were present. There were no plasmodia. The Wassermann reaction was negative.

The picture seemed so unusual that an absolute diagnosis could not be made at this time, but one of us (F. R. T.) felt that a few days of observation under extralim treatment would do no harm, and an atypical pernicious anemia seemed a possibility, though the definite level and rapid development of symptoms made that diagnosis difficult to defend.

We saw the patient again four days later and not only was she no better, but the level of sensory disturbances had risen about three inches. Then we made a definite diagnosis of tumor of the spinal cord and referred her to the Duke University Hospital at Durham, N. C. for further study, and if deemed wise, operation to remove the tumor.

At Duke she was examined by Dr. Frederic M. Hanes, professor of medicine and he agreed with the diagnosis, though no cause for the anemia was found. After a few days of observation and building up she was transferred to the surgical service of Prof. Deryl Hart, who operated on her February 13. Previous to this a cysternal injection of iodized poppy-seed oil had been done which showed a definite subarachnoid block at the level of the fourth, fifth and sixth thoracic vertebrae. An extradural tumor was found springing from the outer surface of the dura which almost encircled the cord involving the anterior and posterior roots on both sides, in the region of the fifth and sixth thoracic vertebrae. It was of unusual difficulty to remove, but after long patient work involving removal of part of the dura and covering the exposed cord with fascia the operation was completed. The pathologists' report was endothelioma. Our latest information is to the effect that the patient is rapidly regaining motion and sensation where these were impaired and complete cure is hoped for.

COMMENT

Having seen the tumor in situ we find it difficult, if not impossible to explain the absence of pain. Before operation we thought of the possibility of an intramedullary tumor, but had this been present it is highly probable that the pathways going through the sacral roots would be involved also with sensory disturbances posteriorly sphincter disturbances and so on. During her stay in the hospital before operation, the anterior sensory symptoms kept rising higher till they reached a level

near the nipples. She also began to show very slight incontinence of urine. The adductor spasm resulting from percussion over the lumbar spine is also rather hard to explain. If the tumor caused it, as presumably it did, why did not percussion over the thoracic spine in the tumor region also produce it? We do not know. We merely record the fact.

Pernicious anemia explains the great majority of cases of severe anemia with cord symptoms but appears to have been excluded in this case, though it was considered for a few days as possibly the sole diagnosis. The association of a rather severe anemia of obscure cause with a benign tumor of the cord is unique in our experience and seems worthy of record.

Therapeutics

THE THERAPY OF THE COOK COUNTY HOSPITAL

EDITED BY BERNARD FANTUS, M.D.
CHICAGO

NOTE—In their elaboration these articles are submitted to the members of the attending staff of the Cook County Hospital by the director of therapeutics, Dr. Bernard Fantus. The views expressed by various members are incorporated in the final draft for publication. The series of articles will be continued from time to time in these columns.—ED

ULCER THERAPY

An ulcer is a defect of the body surface entailing the loss of at least its epidermal covering. It may or may not be infected. It may be large or small, deep or shallow, acute or chronic, painless or painful with exuberant granulations, indolent or indurated. It may show a tendency to spread owing to virulent infection such as chancroid, to granulomas such as syphilis, tuberculosis or lepra, to malignant disease such as carcinoma or sarcoma, or merely because of malnutrition of the tissues. In accordance with these different conditions, various ulcers need different treatment.

Because of the special therapy that they require, all ulcers with a tendency to spreading and ulcers in special locations will be eliminated from this discussion, as these will be discussed under their respective headings such as corneal ulcer, peptic ulcer, ulcers of the colon and fissure of the rectum, as well as varicose ulcer or chancroid (q v).

CLEANING UP

According to the definition that infection means the "successful invasion of tissue by micro-organisms," disinfection of an ulcer is possible only by sacrificing the invaded tissue in order to destroy the invaders at the same time for no agent is known as yet that will kill bacterial cells without at the same time destroying the more highly organized tissue cells, when these two are in intimate relation to each other. As such treatment will make the ulcer larger than it was before, it is justified only in ulcers that have a tendency to spread because of progressive invasion, as chancroid (q v) or lupus (q v), though even in these conditions gross cauterization is being abandoned. When on the other hand, spreading ulceration is due to loss of proper blood or nerve supply as in arterial thrombosis of the legs or in perforating ulcer of the foot, the use of disinfectants would merely add grave chemical injury to tissue dying from intrinsic deficiency of nutrition and would increase the damage.

Drainage, i. e., encouraging the discharge, is the chief measure for removing infection with minimum harm to the invaded tissue. In providing drainage one is reinforcing a curative tendency of nature. Drainage is indicated when an ulcer is acutely inflamed, its surface is secreting profusely, and its edges are infiltrated. After it is cleansed as far as possible with Solution of Hydrogen Dioxide, it is treated with hot Boric Acid dressings, under water-proof covering which are changed two hourly during the day and every four hours during the night until healthy granulations have made their appearance and the infiltration of the edges has largely disappeared. Superior probably to the hot boric dressing is the hot 10 per cent Magnesium Sulphate solution compress which, being hypertonic, not only prevents maceration but also, by the exosmotic currents it induces aids in the cleaning up process, and it is analgesic besides. For foul-smelling sores, constant immersion for a time in a warm (95 to 100 F.) dilute solution of Potassium Permanganate is the quickest way of rendering them inoffensive. The solution is made and kept rose colored. Frequent irrigation with such solution is next best. After the odor has been overcome, hot boric dressings may be applied. An exception to the employment of macerating (occlusive) moist dressings must be made in case of ulcers surrounded by dermatitis. So-called eczematous ulcers require uncovered compresses. For moistening these Solution of Aluminum Subacetate, diluted 1 to 10, might be the most useful primary dressing to be followed as soon as the ulcer appears clean, by whatever local treatment the surrounding eczema (q. v.) calls for.

Once a shining granulating surface has been secured, it is fairly resistant to infection, so long as this surface is not traumatized, as occurs e. g., on pulling off adherent dressings, which also delays the healing. Hence one of the most important principles in the treatment of all ulcers is the prevention of the sticking of dressings. Moist dressings accomplish this only so long as they are moist. They must therefore be renewed at intervals of not more than three or four hours. Moist dressings should not be continued, however, longer than is necessary to "clean up" the ulcer, for they are also responsible for waste of a great deal of reparative material. So long as there is infection, this sacrifice is necessary. As soon as the need for antiseptic therapy has ceased, moist dressings should be discontinued. Dry absorbent dressings are even more objectionable because, in addition to draining away a lot of reparative material, they become adherent to the surface, so that on daily renewal of the dressing a day's growth of reparative cells may be pulled off, thus delaying the healing indefinitely while inflicting pain on the patient, who comes to dread the dressing ordeal.

PROTECTION

When an ulcer is or has become fairly clean, its chief need is some form of protection to act in the place of the epidermis, the missing natural protectant against physical injury and infection.

(a) John E. Cannaday advocates wire gauze screens to protect ulcers and allow contact with air to minimize drainage and promote healing while permitting exposure of ulcers to warm, dry air and to sunshine or to electric light treatment, if the former is not available.

Light "mouse proof" wire mesh is cut to the size necessary to make an adequate shield over the wound. The edges are bound with adhesive plaster and shaped

so as to fit about the wound, at times holding the edge away from the area by means of a felt support, as for instance in case of a screen encircling the finger. These screens are anchored in place by pieces of adhesive plaster or otherwise.

Absorbent dressings do no harm on a wound in which no raw surface is exposed, but, if a raw surface is present, they do a great deal of harm. The contact of absorbent dressings with granulating surfaces causes a foreign body reaction—a profuse discharge that wastes reparative material. It keeps the skin edges in a moist, macerated and water-logged condition and macerated epithelium does not mature well. The tearing away of epithelial new growth with adherent dressings still further delays healing. The longer healing is postponed the more fibrous scar tissue forms, which still further discourages the reparative process. The ideal condition for epithelization consists of a clean wound covered with a dry, well adherent scab that remains *in situ* undisturbed, until healing is complete, at which time spontaneous detachment occurs.

(b) The paraffin film expedites healing probably more than any other dressing by furnishing more physiologic condition for healing. It is firmer and gives a better immobilization of the part and support to the growing epithelium than most others. It protects the surface cells against drying, which, being an enemy to cell life, makes proliferation of the surface cells impossible and, thus, delays healing. Indeed, in all air exposure dressings, surface cells are killed and these form the protective film essential for the growth of the cells beneath. Applied as the paraffin film is to extend well over the healthy skin, it soon becomes lifted off the raw surface by accumulation of exudate. This fluid furnishes the best possible culture medium for the proliferating tissue cells. At the same time there is less exudate than with absorbent dressings, either dry or wet, so that healing occurs with comparatively little waste of reparative material. Being perfectly bland, the paraffin does not kill cells as do most antiseptic dressings and as even drying does, nor are the living cells likely to be pulled off or damaged as occurs with adherent dressings.

"Surgical Paraffin" (of a melting point at or below 50 C.) is employed for this dressing. Medication with antiseptics is useless, as the paraffin hermetically seals the chemical against access of solvent. The paraffin, shaved or broken into small pieces, is put into a perfectly dry sterilized receptacle, which, well covered to prevent water from splashing into it, is placed in a larger vessel partly filled with water that is kept boiling until nearly all the paraffin is melted. Should water get into the melted paraffin, it may cause a burn when the dressing is applied. Before applying it, one should take the temperature of the melted paraffin or else test by dropping a little of it on the back of one's hand. It is not likely to be too hot if there is still some unmelted paraffin present. The ulcer is carefully cleaned by aseptic or antiseptic irrigation and the removal of loose dead tissue. One then dries it by laying a piece of sterile gauze over it gently touching and blotting the gauze by wads of dry gauze or cotton. The surface should never be wiped, and care should be exercised to avoid bleeding or infection. The use of a hot air douche to expedite drying is convenient but not essential. To minimize the distress caused from the application of the first coat of melted paraffin to the sensitive raw surface, the latter is painted first with

sterile Liquid Petrolatum Over this a thin layer of sterile cotton is applied, which is followed by a film of the melted paraffin laid on by a series of gentle pats, rather than by painting it on. The dressing should be carried half an inch or more over the healthy skin, to which it adheres, completely sealing the wound, the skin being more sensitive than a raw surface, patients may complain of pain when the application to the skin is made. However, provided the temperature is at or near the melting point of paraffin, there is little danger of a burn. After the first film has been gently laid on, a second fairly thick layer may be applied by painting. The dressing may now be finished by covering it with a gauze bandage, or else a piece of gauze may be placed over the paraffin and a muslin roller bandage put on.

At first the dressing needs to be changed once every twenty-four hours, later it may be left in place for forty-eight hours or longer. In removing the dressing, it is best to slit it through with scissors, taking care, of course, not to wound the raw surface. Owing to the accumulation of fluid underneath it, the film may then be rolled back without the least pain or danger to the ulcer. A fresh dressing is then reapplied. If pus accumulates under the paraffin film, as it may if the ulcer is not sufficiently aseptic—for the serum accumulating under the film is a good culture medium not only for cells but also for microbes—or if other local or systemic symptoms of infection manifest themselves,

PRESCRIPTION 1—*Petrolatum Cerate*

℞ Paraffin	30.00 Gm
Petrolatum	60.00 Gm
Mix by melting and sterilize	
Spread on gauze in a sterile manner and apply to ulcer	

application of moist dressings for a few days is required.

(c) As cerate is a salve of a melting point higher than the temperature of the human body surface, dressing an ulcer with such a preparation is superior to using Castor Oil or Petrolatum. The latter melts at body temperature and both soak through the dressing rather than stay on the surface where the fatty film is needed. As good as any preparation for the purpose is a mixture of Paraffin one part and Petrolatum two parts (prescription 1), which is less troublesome to apply than the paraffin film but probably not quite so efficient, as it does not retain the wound secretion, the "culture medium for cells," quite as well. If the raw surface is not very extensive, cerate serves well enough. If the ulcer is painful, 10 per cent of ethyl aminobenzoate (anesthesine) may be incorporated with advantage (see prescription 4, Therapy of Pain).

(d) Silver foil has been suggested as a dressing especially suitable for deep burns of limited extent, such as those resulting from electric currents. Silver foil clings to the surface, it is bacteriostatic, it forms a closed moist chamber for accumulation of wound secretion to serve as a culture medium for the proliferating cells, it keeps dressings from sticking and it is remarkably analgesic. Keloid formation seems to be less marked under this than under almost any other treatment.

STIMULATING GROWTH OF CONNECTIVE TISSUE

While the rather fresh raw surface of an acute ulcer is too sensitive to tolerate the application of anything other than bland protectants such as those described, there soon comes a time when healing can be accelerated

by increasing the blood supply and stimulating the proliferation of cells. Such stimulative treatment is demanded by the indolent ulcer, i. e., an ulcer that remains without signs of healing and shows no tendency to exuberant granulations or to callous margin formation. All irritants of appropriate strength stimulate the growth of connective tissue and most of them favor its growth more than they do the proliferation of the epithelial cells, probably because the latter are more highly organized than the former. If the employment of nonspecific irritants is continued too long, exuberant granulations, which delay final healing, may soon have to be contended with. Until the ulcer bed is well filled, such irritants are indicated. Their use must be discontinued as soon as a tendency to exuberant granulations manifests itself.

(a) Radiant energy is especially indicated in the treatment of extensive ulcers, e. g., burns (q. v.), particularly if the part seems to be poorly supplied with blood. Then more or less continuous direct exposure to the heat of the electric "bake" or "cradle" may be the most convenient way of accomplishing the result. Ultraviolet rays or sunshine must be dosed more carefully. The latter rays are probably indicated especially when a remnant of infection must be cleared up, for they may have a certain degree of antiseptic value. For fresh granulations not more than a mild erythema dose is advisable. When the local reaction has disappeared, another exposure may be given, usually in about a week. Excessive exposure may produce necrosis. In chronic fibrous lesions, massive dosage may be required so as to secure an intense reaction even to the degree of destroying the unhealthy tissue and securing a fresh granulating surface. As granulating surfaces are more sensitive to radiant energy than the skin, dosage for them must be more carefully regulated. The wire screen dressing is especially suitable when the use of radiant energy is contemplated.

(b) Rosin Cerate, by reason of the small amount of turpentine contained in the rosin, might be used as the succedaneum to the petrolatum cerate as soon as the initial irritability of the ulcer has subsided. Among all the possible irritants that might be used for stronger action, Balsam of Peru might be said to be "time honored," especially in the treatment of bed sores. Its disadvantages are that it has an odor which becomes objectionable when continually under one's nose and that it produces a rather indelible stain on fabrics. On the other hand, it is not only a good stimulant to healing but also bacteriostatic and keeps dressings from sticking. It might be added in varying proportions to rosin cerate. It may be used in the form of a paste with Zinc Oxide (prescription 2) or mixed with Castor Oil in various proportions, e. g., equal parts, and is soon tolerated in full strength, poured directly on the sore or as "Balsam Gauze," i. e., gauze strips impregnated with Balsam of Peru, that are then covered with wire screen or absorbent dressing according to the amount of discharge. When applied too strong, it produces an initial stinging and burning sensation. Compound Tincture of Benzoin (the friars' balsam of the Middle Ages) forms, after evaporation of the alcohol, a varnish that is not only protective but also stimulant to healing. It is especially suitable as a dressing for rather small and somewhat indolent sores.

(c) Sympathectomy, periarterial or otherwise, may cause prompt healing of a particularly refractory ulcer,

STIMULATING EPITHELIAL GROWTH

As an ulcer is not healed until completely covered with epidermis, the problem presents itself not infrequently of stimulating the multiplication and maturation of epidermal cells. Reducing agents have a special reputation for having this effect. Can it be that, by lessening the supply of available oxygen, they make the developing cell act as though it were farther away from the blood supply than it really is and undergo earlier keratinization? Scarlet red ointment is used in 5 per cent strength. It probably has its best use applied

PRESCRIPTION 2—*Balsam of Peru Paste*

R	Balsam of peru	10.00 Gm
	Zinc oxide	40.00 Gm
	Castor oil	50.00 cc
Mix	Label: Spread on gauze and apply to ulcer	

merely to the growing epithelial margin for a day or two alternating with soothing ointment. Gauze may be impregnated with scarlet red ointment or a compound (prescription 3) as especially recommended by Adalbert G. Bettinan (1931) for preparing ulcers for skin grafting and for favoring the "taking of the grafts." Short pieces of the red gauze are cut and laid directly on the wound, completely covering it with a single layer. A sufficient layer of dry sterile gauze is applied and the whole kept in place with a bandage. When discharge appears at the surface of the dressing the outer layer

PRESCRIPTION 3—*Compound Scarlet Red Ointment*

R	Oxyquinoline sulphate	0.60 Gm
	Chlorbutanol	2.40 Gm
	Liquid petrolatum	4.00 cc
	Scarlet red ointment 5 per cent	120.00 Gm
Mix	Melt and immerse rolled gauze bandage until all bubbling has ceased. When cool it is ready for use. It keeps well. The outer layer or two of the bandage is discarded as it is completely covered with ointment and only that portion of the gauze is used whose interstices are open.	
	This prescription may be unnecessarily complicated. Scarlet red ointment applied in the same manner in gauze bandage works quite well.	

is changed, but the red gauze is left in place until it comes off easily, which may not be until complete epithelization has occurred. Thiocresol compresses advocated of late (Reimann, 1930), probably deserve trial in extensive ulcers. Because thiocresol is very unstable, it should be always freshly prepared in a 1:10,000 dilution (prescription 4). It is poured on sterile gauze, which is applied directly to the wound and covered with waterproof material, so that changing of the dressing may not be required oftener than every two hours. Such dressings are best alternated after forty-eight hours

PRESCRIPTION 4—*Thiocresol Stock Solution*

R	Thiocresol	0.10 Gm
	Alcohol	50.00 cc
Mix	Label: Mix 5 cc with 100 cc of distilled water to give a 1:10,000 dilution. Prepare fresh solution for each change of compress.	

periods with simple dressings, such as compresses of Physiologic Solution of Sodium Chloride. The chief disadvantage of thiocresol is its offensive smell.

REMOVING IMPEDIMENTS TO HEALING

In disease, as in warfare, conditions change so that what may have been correct tactics one day may be wrong a few days later. The three most important impediments to healing are (1) exuberant granulations, (2) a callous ulcer margin and (3) ulceration completely encircling a limb.

1. Exuberant granulations have to be destroyed and then restrained from redeveloping. There may be a sufficient growth of them in neglected cases to require curettement or even trimming off with scissors.

(a) Silver Nitrate cauterization usually suffices to restrain their growth, if applied once or twice a week. In applying the lunar caustic stick or crystal, one must keep a respectful distance away from the visible epithelial margin. Indeed, if one looks sharply, one may distinguish the zone of advancing epithelial cells as a dull pearly haze in contrast with the shining naked granulations. It is easy to sacrifice this microscopic layer of pioneer epithelial cells and with it the prospect of early healing. One "thorough" cauterization may set healing back by a week. When a tendency to exuberant granulations manifests itself, the dressing should be merely protective (as described under Protection), excepting as far as stimulation of epithelization is concerned.

(b) An exception to this rule occurs in case of anemic ulcers with pale, flabby granulations. In these the stimulating astringency of the Copper Sulphate crystal or even of Zinc Chloride is preferable to silver nitrate cauterization. It should be followed by dry treatment, e.g., dusting with Thymol Iodide, and a compression bandage.

(c) For restraining the development of exuberant granulations there is nothing better than the compression bandage, which also seems to favor ingrowth of epithelium. It is secured either by firm strapping with elastic adhesive plaster, applied directly over the naked granulations and a liberal area of the surrounding skin or else, if moist or cerate dressing is desired, a rubber sponge may be incorporated under a firmly applied bandage (cf. varicose veins).

2. The callous ulcer with edges of indurated edema of often cartilaginous hardness, cannot heal so long as the induration is permitted to remain. It indicates the use of

(a) Hydrotherapy. Hot circular compresses covered for maximum effect with waterproof material continued possibly for several days may produce a macerating effect on the tissues and increase the blood supply to the part to such an extent as to alter the immediate aspect of the ulcer as well as its ultimate prospect of healing. Local hypodermoclysis of Physiologic Solution of Sodium Chloride into the surrounding tissue may assist this softening effect by its lymphagogue action.

(b) Pressure. By means of adhesive plaster, an elastic bandage or a rubber sponge dressing (see varicose veins) accompanied by a fair amount of muscular exercise, so as to exert a pumping action on the circulation, pressure may help in the absorption of the callous margin softened by hydrotherapy, so that these two measures should be used in succession or alternation, e.g., the pressure bandage during the day, the compress during the night.

(c) Irradiation. The absorption of the infiltration of the edges may be favored by roentgen rays in fractional doses (140 kilovolts, 0.25 mm of copper, 1 mm of aluminum, 75 roentgens) or perhaps more safely by an occasional erythema dose of ultraviolet rays or by daily graduated doses of the sun's rays.

(d) Surgery. When the foregoing methods fail, there are two ways of forcing healing, after a thorough curettement. One is to make incisions through the indurated margins radiating from the center of the ulcer, like the spokes of a wheel. The incisions must penetrate the deep fascia and extend for one or two inches beyond the margins of the ulcer. The other and more usual

method is complete excision of the ulcer, to be followed by skin grafting as soon as healthy granulations have been secured

3 An ulcer encircling a limb may require amputation if plastic operations fail

SKIN GRAFTING

Skin grafting is mandatory in the larger defects at the earliest possible moment, i e., as soon as a bed of healthy granulations of deep red "raw beef" color has been secured, and especially in those ulcers in which cicatricial contraction is liable to lead to deformity. As grafts from another individual (isoplastic grafts) are less likely to take, autoplasmic grafts should be preferred. Of the two different methods of skin grafting, the free and the pedicled graft, each has its own indications

(a) The free grafts are taken down through the germinal layer of the epidermis, not deep enough to cause much bleeding. "Seed implants" (Wilhelm Braun, 1920) are the most uniformly successful variety, as they are likely to take even in the presence of infection. The site having been anesthetized by infiltration with 2 per cent solution of Procaine Hydrochloride, the skin to be transplanted is picked up on the point of a hypodermic needle and snipped off with sharp scissors or sheared off with a sharp knife or razor. It is then cut into small pieces, "about half the size of a grain of wheat," and these are implanted deep in the granulating surface about 1 to 1.5 cm. from one another. It does not matter which side is up. Warm Physiologic Solution of Sodium Chloride compresses are applied for two days, to be alternated with thio cresol compresses (prescription 4) for the next two days. In the ambulatory patient, gauze impregnated with compound scarlet red ointment (prescription 3) is used from the very beginning, or else silver foil is applied. If the granulations have a tendency to be exuberant, adhesive plaster strapping or rubber sponge needs to be incorporated in the dressing. The advantages of the seed implants are that they are most economical of skin and that they will take even if the surface is not aseptic. Their disadvantage is that they grow unevenly and ultimately develop into a mottled skin with islands of pale color surrounded by areas of redness. Hence they are not suitable for exposed surfaces. In spite of this it might be well to cover with these seed implants any ulcer larger than a dollar, no matter where located, as it can be made to heal more rapidly by their use. If further plastic surgery is needed it can be done at a later date, the rapid covering of the wound and granulations by these new grafts lessening cicatricial contraction.

Thiersch grafts, in which strips of about half the thickness of the skin are used, have the advantage of quicker healing and of producing a smoother surface than the seed implants and a relatively noncontractile new skin, but they leave a thin and rather vulnerable scar and are less likely to take in the presence of infection. The surface must therefore be carefully prepared for their reception. It must be made as healthy and aseptic as possible and there must be little or no pus. The superficial granulations if irregular, are curetted away with a very light touch and if a line of cicatrization has formed it is best to remove this as subsequent ulceration frequently occurs at just this place. All hemorrhage must be thoroughly checked before the grafts are put in place, because blood clots make adhe-

sion impossible and result in infection. The skin from which the graft is to be taken is put on the stretch and, with a keen razor kept wet with Physiologic Solution of Sodium Chloride, strips from 1 up to 12 inches long are removed, transferred to the wound on the razor blade, and spread evenly and closely on the prepared raw surface by means of probes. If it is more convenient, the strips may be temporarily immersed in warm sterile Physiologic Solution of Sodium Chloride. No antiseptic solution must be permitted to come in contact with the grafts. The first thing to be laid on these grafts should be some material that will keep the grafts in place and favor their adhesion to the raw surface without permitting the dressing to stick. This may be found in the red gauze (prescription 3), in silver foil, or in sterile rubber tissue. When the red gauze is used, it is cut into short pieces and the entire surface is covered with it completely, overlapping being reduced to a minimum. A sufficient thickness of dry gauze is then applied to carry away the secretions and protect the wound. With the foil or rubber tissue, gauze impregnated with sterile oil or petrolatum is employed. It is very important to immobilize the part sufficiently to prevent dislodging the grafts, which adhere but slightly to the raw surface during the first few days. Dressings should not be changed for the first four or five days, and dressings that adhere should never be pulled off but left in place until they come away easily.

The full thickness graft is useful when greater flexibility is required than that furnished by the thin grafts. These grafts must be freed from fat and subcutaneous tissue. They must be sutured accurately and under slight tension over an aseptic and dry surface, and firm, even pressure must be maintained over the graft during the period of healing. Their chief disadvantage is that the slightest infection, such as is present in most granulating surfaces, is sufficient to cause necrosis and loss of the graft. Hence it is more suitable in the treatment of scar tissue contractures after an ulcer has healed completely than in the treatment of ulcers as such.

(b) The pedicled graft permits transplantation of subcutaneous tissue including fat, which requires its blood vessels to survive. Pedicled grafts are especially indicated in cases in which subcutaneous tissue is required to restore the contour of parts, as in ulcers involving the face. The pedicled graft produces a much more flexible covering than any other kind of graft and hence finds its field of greatest usefulness in cases in which important anatomic structures, such as tendons, blood vessels, nerves, bones or joints, lie exposed in the bottom of the wound. It is more certain to survive, even in the presence of a slight degree of superficial infection. Its technic, being a matter of the art of plastic surgery, would require too much space to be adequately discussed here.

PREVENTION OF CICATRICIAL DEFORMITY

From the very first, the physician having charge of a case of extensive ulceration must take care to prevent deformities due to scar tissue contraction. This is done by

(a) Posturing the affected part, if necessary with the aid of splints or other mechanical devices, so as to force the newly formed tissue to cover the greatest span required by function, e g., maintaining the arm in full flexion for a large ulcer on the posterior surface of the elbow, thus antagonizing nature's tendency to

economize tissue growth by lessening the size of the ulcer by contraction during the process of cicatrization

(b) Exercise When joints are involved in the ulcer the patient, at the time dressings are changed, should put the joint repeatedly through all its possible movements. This is many times best accomplished by performing the exercises in a warm bath

(c) Early skin grafting

CORRECTION OF SYSTEMIC ABNORMALITIES

Syphilis and diabetes mellitus are two conditions that are particularly prone to interfere with healing processes and that require appropriate treatment. The presence of anemia, nephritis, myxedema, avitaminoses and general malnutrition requires early recognition and energetic treatment, for good tissue growth needs an abundant supply of healthy blood

Council on Physical Therapy

THE COUNCIL ON PHYSICAL THERAPY HAS AUTHORIZED PUBLICATION OF THE FOLLOWING REPORTS

HOWARD A. CARTER, Secretary

HANOVIA ULTRAVIOLET METERS ACCEPTABLE

The Hanovia Ultraviolet Meter, marketed by the Hanovia Chemical and Manufacturing Company, Newark, N. J., is designed and calibrated for the measurement of the ultraviolet radiation energy of wavelength 3130 angstroms and shorter from the quartz mercury arc lamp and from the 60 ampere C carbon arc

The meter consists essentially of a light sensitive cell mounted behind a filter glass transmitting radiations of wavelengths between 2500 and 4000 angstroms and a sensitive micro-ammeter for the measurement of the electric current generated within the cell when the cell is exposed to ultraviolet radiations. The photo electric cell used is of the dry electronic type and should not be confused with the usual photo-electric cells, which require auxiliary electrical circuits and an electrical supply. The photocell used is manufactured by the Weston Electrical Instrument Company of Newark, N. J.

The Hanovia Ultraviolet Meter is available in two forms, namely, an indicating instrument and a recording instrument. The indicating instrument is portable and completely contained within a quartered grain oak meter box $8\frac{1}{2}$ by $4\frac{1}{4}$ by $8\frac{3}{4}$ inches provided with a cover and a leather handle. Provision is made within the meter box for the target (photocell) an electrical cord for attaching the target to the meter instrument and an instruction book. The entire instrument weighs $7\frac{1}{2}$ pounds.

The target of the indicating instrument is a light bakelite container conveniently shaped for handling, and has mounted in its broad surface the filter window, which admits the ultraviolet to the sensitive cell below, and a metal disk on which is inscribed a calibration factor by which all readings on the accompanying micro-ammeter must be multiplied in order that readings may be converted into microwatts per square centimeter of ultraviolet radiation of wavelength 3130 angstroms and shorter, for the quartz mercury arc. The target is permanently connected electrically to the micro-ammeter which is provided with multipliers permitting the employment of the ultraviolet meter for a range of intensities extending from about 10 microwatts per square centimeter to about 10,000 microwatts per square centimeter. The instrument is intended for intermittent use.

The Hanovia Recording Ultraviolet Meter is designed for continuous operation and gives a written record of the ultraviolet radiation in the spectral band of wavelength 3130 angstroms and shorter that falls on the target. The target is

essentially the same as that employed in the indicating meter excepting that for continuous operation and for the protection of the cell and filter from humid conditions these elements are sealed within a copper container provided with a transparent quartz window. The recording micro-ammeter employed is the Engelhard Type S (U. S. Weather Bureau Circular Q, 1931). This instrument automatically provides a timed and written record of the ultraviolet energy at half minute intervals on a chart roll.

A special form of the Hanovia Recording Ultraviolet Meter with auxiliary equipment can provide constant voltage regulation for quartz mercury and carbon arcs and in the instance of the Hanovia quartz mercury arcs operated on the Bird electrical circuit and at initially lower than maximum burner wattages, can correct automatically for any ultraviolet losses resulting from deterioration of the quartz envelop by gradually increasing the burner wattage by increments as the quartz envelop becomes more opaque to the radiation.

The recording ultraviolet meter is normally calibrated for a range of ultraviolet intensities in the band of wavelengths 3130 angstroms and shorter extending from 100 to 10,000 microwatts per square centimeter. When employed as a control instrument, the meter is frequently calibrated to record the energy as falling on the irradiation surfaces instead of the actual light energy falling on the target. When employed in this manner, the target, the irradiation surfaces and the burner must be located in absolutely fixed positions.

All Hanovia ultraviolet meters are calibrated by the Hanovia research staff employing reference instruments calibrated at the National Bureau of Standards, Washington, D. C. When especially requested (and subject to a reasonable delay), meters may be calibrated at the National Bureau of Standards and supplied with its certificate.

It is claimed that the meter employed with the proper factors and multipliers and recalibrated at the proper time intervals (see later) will give a measure of the ultraviolet energy of wavelength 3130 angstroms and shorter, from the quartz mercury arc and from the 60 ampere C carbon arc, with an accuracy of plus or minus 5 per cent.

The permanence of the response of the Hanovia Ultraviolet Meter has been established. The photonic cell itself has been found to have a very small fatigue; the response decreases from 2 to 3 per cent with normal temperature increases; there is a continual decrease in sensitivity as the cell ages.

These factors are compensated for as follows. The target must be exposed to the radiation for several minutes before a reading is taken. A constant reading (with a constant light source) will then be obtained. Provided the target is not subjected to high temperatures (60 C and more) the factor of temperature will not enter into the usual measurement because the cell will not warm sufficiently during the brief exposure to result in any readable differences due to temperature effect. These factors are compensated for as follows. The target must be exposed to the radiation for several minutes before a reading is taken. A constant reading (with a constant light source) will then be obtained. Provided the target is not subjected to high temperatures (60 C and more) the factor of temperature will not enter into the usual measurement because the cell will not warm sufficiently during the brief exposure to result in any readable differences due to temperature effect.

The aging of the cell itself is very slow, extending apparently over years and amounting to a few per cent each year. Recalibration readily accounts and corrects for such changes. It is interesting to note that Prof. Paul Gleason of the department of physics, Colgate University in the *Review of Scientific Instruments*, October 1932, has reported similar observations for the photonic cell exposed to visible light.

Hanovia Recording Ultraviolet Meter

In the case of industrial and milk lamps in which the target may be exposed continuously to the radiation, after from three to four hours of operation the response of the cell has decreased the 2 to 3 per cent, and because of the constant intensity feature of these lamps the ultraviolet intensity actually increases from 2 to 3 per cent above the initial value.

The glass ultraviolet filter employed over the cell has been another point of consideration. All indications have pointed to the solarization of this filter as one of the most important factors influencing the constancy of response of the ultraviolet meter. Presolarization of the glass has been considered as a possible means for eradicating this factor, and experiments are now in progress to determine whether such procedure is productive of practical results.

The micro ammeters employed are well known instruments of the highest quality. The switches used in the indicating meter are also the best obtainable but these have in a few instances been responsible for a sudden loss in instrument sensitivity. The recording meter does not employ any switches and so is not subject to such a possible difficulty.

The Hanovia research organization has concluded that the foregoing somewhat troublesome observations were greatly outweighed by the convenience and desirable features of the meter. At the most they would be greatly minimized by frequent recalibration, certainly a recommendation for any quantitative radiation measurement device. With this in mind each meter at the time it is delivered is accompanied by a "recalibration notice" advising resubmission of the meter to the Hanovia Laboratory at definite time intervals, three and six months, for check and recalibration. The Hanovia Company is so interested in having ultraviolet radiation measurements common practice and on the same reliable basis as electrical measurements that it is contracting to do this recalibration without charge to the meter users. Provision is also made for periodic recheck of all recording ultraviolet meters in their working location, and any adjustments that may be necessary can be made without interruption of operation.

Measurements made by the Hanovia Laboratory have indicated that if a target is exposed continuously for 1000 hours to ultraviolet radiation of wavelengths 3130 angstroms and shorter, $1,500 \text{ mw/cm}^2$, the response of the meter at the end of that time will be decreased by about 25 per cent from the initial value. Since there are 365 days in a year and it seems unlikely that the indicating meter will be used more than an hour per day (actual exposure), 1000 hours represents about three years' usage. A recalibration of the instrument each three to six months when so used, should keep the instrument within the desired degree of accuracy plus or minus 5 per cent.

The target of the recording ultraviolet meter is very likely to be exposed for longer periods daily. The loss in sensitivity per hour is about the same for the recording meter as for the indicating meter, but the loss per day will most certainly be larger. When the recording meter is used for a constant intensity control, the ultraviolet intensity cannot fall below the predetermined value set and indicated on the scale unless the burner has reached the limit of its useful life or the ultraviolet meter has not been recalibrated according to schedule. On the other hand as a result of the gradual lowered response of the target there results a gradual increase in the burner wattage and therefore in the ultraviolet output of the lamp amounting on the average to 25 per cent increased intensity per hundred hours of operation. Thus if the measured intensity were $5,000 \text{ mw/cm}^2$ initially after 100 hours of target exposure the intensity of the lamp would be $5,125 \text{ mw/cm}^2$ although the meter record would still indicate an intensity of $5,000 \text{ mw/cm}^2$. Since a 10 per cent increase in intensity is within the limits of biologic evaluation recalibration of the meter every few hundred hours of use will maintain a practical balance.

The Hanovia ultraviolet meters within the limitations disclosed are suitable for the measurement of the ultraviolet component of wavelength of 3130 angstroms and shorter from the quartz mercury arc and from the 60 ampere C carbon arc. The meter may be used for the measurement of other light sources only when specifically calibrated for them. The meter cannot be used for the measurement of the ultraviolet component in sunlight satisfactorily.

The Council investigated this meter in a laboratory and a clinic. The results obtained were substantially the same as reported. The Council, therefore, includes the Hanovia Ultraviolet Meter in its list of accepted devices for physical therapy.

WESTINGHOUSE PHOTO-ELECTRIC RECORDER ACCEPTABLE

Manufacturer, Westinghouse X-Ray Co., Inc., Long Island City, N. Y.

The Westinghouse Photo-Electric Recorder provides a continuous record of the intensity of light. The record furnished is in the form of permanent graphic charts, each recording the rate of intensity every minute during a period of several hours. This instrument is particularly valuable for the recording of intensity in the ultraviolet portion of the spectrum, and it can be supplied to respond only to any of several well defined wavelength bands in this region.

A typical example of the use of this instrument is the measurement and recording of ultraviolet intensity in the irradiation of fluid milk. The graphic charts produced by this instrument can be filed away in chronological order as permanent evidence of the rate of irradiation intensity during every minute of each working day.

The instrument (fig. 1) consists of a light-sensitive photo cell with necessary direct current rectifier for energizing it, a relay tube and condenser circuit through which the photo-electric currents are fed, and a graphic recording mechanism. It is operated from any 60 cycle alternating current wall plug the total power consumption being about 25 watts. It can also be supplied, on special order for 25 cycle apparatus. No vacuum tube amplifiers are used.

The instrument is housed in two units interconnected by a flexible cable. The smaller contains the light-sensitive photo cell relay tube and condenser. The larger contains the rectifier and chart movement mechanism.

Principle of operation. A photo-electric cell, sensitive to the desired wavelength band in the light spectrum is supplied with the instrument. Minute electrical currents are passed by the photo cell when exposed to such irradiation and these currents are proportional to the irradiation intensity in that particular band. These minute currents are used to charge a small condenser, which is connected in parallel with a relay tube.

Every time this condenser is fully charged the relay tube "spills over" discharging the condenser and sending an impulse to the recorder. Each of these impulses deflects a recording pen on a moving chart (fig. 2), which is ruled at one minute intervals and moves in time with these rulings. The number of deflections per minute, representing the intensity of light, can be read at a glance at any time, and the charts furnish permanent records of the irradiation intensity for every minute of the time during which the process is carried on.

Photo Cell. The photo-electric cell is essentially an evacuated glass envelop containing a cathode in the form of a metal plate and an anode or target. Light impinging on the metal plate causes it to emit electrons. If a voltage is applied across the tube between the plate and the anode, the electron stream will be directed from the plate to the anode and an electrical current will therefore flow through the tube. The electron emission from the plate is proportional to the intensity of the light; hence the current passed is also proportional to the light intensity. The voltage across the tube is immaterial and has no bearing on the amount of current flowing.

By proper choice of bulb material and of plate material photo-electric cells are constructed to be sensitive only to specific bands in the spectrum. Bulb materials such as glass or Corex pass the longer wavelengths of light but are opaque

Hanovia Indicating Ultraviolet Meter

Fig. 1—Westinghouse Photo-Electric Recorder

REPORTS OF THE COUNCIL

THE COUNCIL HAS AUTHORIZED PUBLICATION OF THE FOLLOWING
REPORT PAUL NICHOLAS LEECH SecretaryVEGEMUCENE NOT ACCEPTABLE
FOR N N R

to the shorter wavelengths. On the other hand plate materials used such as tungsten, titanium and thorium have exactly the opposite characteristics, responding in various degrees to the shorter wavelengths. Hence by choice of a suitable combination of bulb material and plate material, a photo electric cell more sensitive to a particular section of the spectrum can be constructed.

Three of the standard cells available for use in measuring intensity in the ultraviolet region are as follows:

- A cell with a thorium plate and Corex D bulb sensitive within a range of 3200 to 3700 angstrom units
- A cell with a titanium plate and Corex D bulb sensitive within a range of 2700 to 3200 angstrom units
- A cell with a tungsten plate and bulb having an extremely thin indrawn bubble glass window sensitive within the range below 2700 angstrom units

The first two of these cells are mounted behind Corex windows in the photo cell housing. These windows not only keep the photo cell housing dust tight but also are factors in the fixing of the sensitivity range. With the third cell no window is interposed in front of the bulb to avoid filtering out of radiation in the region of the spectrum to which this cell is sensitive.

Recorder The recorder charts are of the disk type and the record appears as a spiral line with the condenser discharge marks crossing it. One chart provides a complete totally visible record for several hours. The chart is marked off with radial lines one minute apart and is rotated by a clock type synchronous motor which of course measures very precise time. Ordinarily the calibration is such that between five and ten condenser discharges occur each minute and it is therefore only necessary to glance at a chart to see whether any serious discrepancies in light intensity have occurred. The length of the condenser discharge marks may change because of line voltage fluctuations or variations of friction of the pen on the paper but this is of no consequence, as the number of discharge marks per unit of time is the only pertinent factor.

Fig. 2—Recorder chart

In the lower part of the recorder housing is mounted the rectifier for the direct current voltage required to operate the photo-electric cell. A type 80 rectifier is used.

Installation The photo cell housing is set up at the calibration distance from the light source in such a position that it will be reasonably free from dust and moisture. The window through which the light enters must, of course, be kept clean. The recorder housing is mounted on a wall at any convenient place, and a plug inserted in an alternating current wall receptacle. The cable connecting the photo cell housing to the recorder is provided with a plug permitting the use of an extension cable if necessary.

To start operation of the recorder a blank chart is inserted and ink placed in the recording pen. Simple adjustments are provided for locating the pen at the proper position on the chart to correspond with the time at which the record is started. Turning the main switch in the recorder housing to the "on" position starts the apparatus. To stop it, it is necessary only to shut off the switch.

The following units are available:

- Photo Electric Recorder W 6095 for ultraviolet radiation complete including photo cell housing relay tube graphic recorder and 100 recording charts for operation on 110 volts 60 cycles alternating current
- W 6096 Same as W 6095 but for operation on 110 volts 25 cycles alternating current

Any one of the three different types of photo cells aforementioned are available. The Council on Physical Therapy therefore voted to include the Westinghouse Photo Electric Recorder in the list of accepted devices.

Following the introduction of the use of gastric mucin in the treatment of peptic ulcer by S. J. Fogelson of Northwestern University (THE JOURNAL, Feb. 28, 1931) a rather extensive series of clinical reports has appeared. Notwithstanding, the Council is of the opinion that further studies are necessary in order to establish thoroughly the value of such therapy. Workers at the Michael Reese Hospital have recently reported seventeen cases of proved gastric or duodenal ulcer relieved symptomatically, following the administration of a mucilaginous plant substance (in contradistinction to gastric mucin) (ILLINOIS MEDICAL JOURNAL, October 1933). The material used in this work consists of powdered dehydrated okra now marketed under the name of Vegemucene by BioVegetin Products Incorporated, which presented the product to the Council for consideration.

Certain advantages are claimed for Vegemucene over gastric mucin by way of palatability, greater gastric tolerance, and convenience of dosage. Probably all three are valid in a measure but the clinical studies made of the product, thus far, are so inadequate as to preclude any possibility of arriving at a fair estimate of the therapeutic value of the substance. The name is objectionable, as it implies that the substance is mucinous or mucoid in character, yet it is not a true mucin as the term is ordinarily employed. It resembles mucin in physical properties only. As may be seen from the respective formulas there is a significant difference chemically. Vegemucene is said to contain water 10.12 per cent, protein 14.4 per cent, fat 1.8 per cent, ash 5.4 per cent and carbohydrate 66.6 per cent. The protein is said to comprise albumins and globulins. On the basis of average analyses of such glycoproteins, the protein nitrogen in Vegemucene could not be greater than 2.4 per cent, whereas that in true mucin is in the neighborhood of 12 per cent. The term Mucene is therefore misleading in fact and false by connotation.

Notwithstanding the very limited studies thus far reported of the use of powdered okra in peptic ulcer, the firm states in one of its advertising brochures that:

Extensive clinical tests have shown Vegemucene to be extremely effective in the treatment of patients suffering from peptic and duodenal ulcer.

It is pointed out that these patients were maintained on a modified ulcer diet which of itself undoubtedly would have effected a significant improvement in the majority of cases. This fact tends to render another exaggerated therapeutic claim more or less invalid.

Vegemucene causes rapid and effective relief from pain and other associated symptoms of peptic ulcer and duodenal ulcer.

Unless it can be shown conclusively that powdered okra is of benefit in the cure of gastric or duodenal ulcerations, there can be no place for it in the therapy of these conditions, and a series of but seventeen cases is inadequate foundation for critical evaluation of the therapeutic worth of any drug.

However inconclusive and inadequate the available studies of Vegemucene in gastric ulcer it appears that the product is intended for use in that least adequately controlled of all series of cases those which do not have the advice of competent gastro-enterologists. The Council has been informed that the Board of Directors of BioVegetin Products Inc., has taken formal action endorsing lay promotion of Vegemucene. Thus the preparation has been thrust definitely into that vast realm of 'ulcer cures' so elaborately exploited to the general public. It should be noted that even were the product sound therapeutically acceptable chemically and named rationally, the

policies of the firm, tending as they do to encourage self medication of insidious and dangerous disease, would alone condemn Vegemucene in the eyes of the conscientious practitioner of medicine.

The Council declared Vegemucene not acceptable for New and Nonofficial Remedies, because it is an unoriginal preparation of powdered okra, marketed under a noninformative and misleading proprietary name, and promoted with exaggerated and unwarranted therapeutic claims to the profession and to the public at large

ACCEPTED FOODS

THE FOLLOWING PRODUCTS HAVE BEEN ACCEPTED BY THE COMMITTEE ON FOODS OF THE AMERICAN MEDICAL ASSOCIATION FOLLOWING ANY NECESSARY CORRECTIONS OF THE LABELS AND ADVERTISING TO CONFORM TO THE RULES AND REGULATIONS. THESE PRODUCTS ARE APPROVED FOR ADVERTISING IN THE PUBLICATIONS OF THE AMERICAN MEDICAL ASSOCIATION AND FOR GENERAL PROMULGATION TO THE PUBLIC. THEY WILL BE INCLUDED IN THE BOOK OF ACCEPTED FOODS TO BE PUBLISHED BY THE AMERICAN MEDICAL ASSOCIATION. **RAYMOND HERTWIG** Secretary

GREEN HILL BRAND MUSHROOMS FANCY BUTTONS—SLICED—SLICED STEMS AND PIECES

Manufacturer—Green Hill Brand Mushroom Farms, West Chester, Pa., subsidiary of Edw. H. Jacob, Inc., West Chester, Pa.

Description—Hot house mushrooms, respectively buttons, sliced and sliced stems and pieces, the same as Jacob Mushrooms, Fancy Buttons—Sliced—Sliced Stems and Pieces (THE JOURNAL, Sept 15, 1934, p 838)

GAZELLE BRAND SEEDLESS RAISINS HORSESHOE BRAND SEEDLESS RAISINS JOCKEY CLUB BRAND THOMPSON SEEDLESS RAISINS MISSION BRAND THOMPSON SEEDLESS RAISINS PANSY THEY R SEEDLESS BRAND FANCY QUALITY RAISINS ROSEDALE BRAND FANCY QUALITY THOMPSON SEEDLESS RAISINS TEMPLE BRAND THOMPSON SEEDLESS RAISINS TULIP BRAND SEEDLESS RAISINS

Packer—Guggenbume & Company, San Francisco

Description—Sun-dried Thompson seedless grapes

Preparation—Raisins, sun dried without artificial heat or chemical treatment are tested for moisture and sugar content mechanically separated from the clusters mechanically graded according to size, freed from foreign material, imperfect fruit and small stems thoroughly washed in mechanical washers, inspected, treated with high pressure steam to remove excess surface moisture, and automatically packed in cartons

OSCAR MAYER'S SLICED BACON APPROVED BRAND

Manufacturer—Oscar Mayer & Company, Chicago

Description—United States Government Inspected dry cured, smoked sliced bacon

Manufacture—Hog bellies, selected for quality of meat and fat, width, length and thickness, are cut down to uniform size, trimmed and spread on racks over night to bring them to a definite temperature. The bellies are individually rubbed with a curing mixture of salt, sugar sodium nitrate and sodium nitrite and pressed into a wooden curing box. No pickle is added to hasten the cure. In a few days, moisture from the meat forms a brine with the salt and covers the bellies. This process of dry-curing proceeds for twenty-one days at a temperature of 3°C. The bellies are removed from the brine soaked in cold water for thirty minutes to leach out the excess salt from the surface tissue, washed, and hung on special frames in the smoke-house, where they are smoked with smoke and fumes of burning hardwood sawdust and gas for from thirty to thirty-six hours at 32-52°C. The bacon is removed from the smoke-house, chilled, skinned, frozen for twenty-four hours automatically sliced onto a metal conveyor belt scaled off into one-half pound packs wrapped in cellophane check-scaled, and packed in cartons holding twelve one-half pound packages. Before being shipped the cartons of bacon are chilled.

All equipment, including the dry-curing box, is thoroughly washed each day. The soaking boxes are washed weekly with sodium hypochlorite and the slicing equipment daily. The girls who pack the bacon wash their hands in sodium hypochlorite every half hour. The plant is United States government inspected. Every ingredient in the curing mixture and the manufacturing process are subject to approval by the Bureau of Animal Industry. The bacon is analyzed periodically by this bureau to check the nitrites present, which cannot be in excess of 200 parts per million.

Analysis (submitted by manufacturer) —

HALE'S PRIDE STERILIZED UNSWEETENED EVAPORATED MILK

Distributor—Hale-Halsell Company, McAlester, Okla.

Packer—Carnation Company, Oconomowoc, Wis.

Description—Unsweetered sterilized evaporated milk, the same as Carnation Sterilized, Unsweetered Evaporated Milk (THE JOURNAL, June 14, 1930, p 1919)

TRISCO FLOUR (BLEACHED)

Manufacturer—Tri-State Milling Company, Rapid City, S. D.

Description—Patent flour milled from hard northern spring wheat, bleached

Manufacture—Selected hard spring wheat is cleaned, washed, scoured, tempered and milled by essentially the same procedures as described in THE JOURNAL, June 18, 1932, page 2210. Chosen flour streams are blended and bleached with benzoyl peroxide and calcium phosphate (one-tenth ounce per barrel)

HOLIDAY OLEOMARGARINE (CONTAINS 1/10 OF 1% SODIUM BENZOATE)

Manufacturer—The Best Foods, Inc., New York City

Description—Margarine containing hydrogenated coconut and peanut oils, pasteurized milk cultured with lactic acid bacilli, salt, and sodium benzoate (not over 0.1 per cent)

Manufacture—The same as Nucoa Oleomargarine (THE JOURNAL, April 22, 1933, p 1238)

Claims of Manufacturer—For use as a bread spread and as a fat or shortening in baking and cooking or for table purposes

SATURDAY, JANUARY 26 1935

PROGRESS OF PLANS FOR ECONOMIC SECURITY

The suggestion made by President Roosevelt in June 1934 that the chief objective of the present Congress would be the enactment of legislation leading to greater economic security for the American people began to find its fulfillment on Jan. 17, 1935. On that day he sent to Congress a message relative to unemployment insurance, old age pensions, federal aid to dependent children, the support of existing mothers' pension systems, appropriations for services for the protection and care of homeless, neglected, dependent and crippled children, and finally additional aid by the federal government to state and local public health agencies and for the strengthening of the federal Public Health Service. As was recently pointed out in an editorial in *THE JOURNAL*, the problem of sickness insurance is more difficult. Of this the President has just said specifically:

I am not at this time recommending the adoption of so-called "health insurance," although groups representing the medical profession are cooperating with the federal government in the further study of the subject and definite progress is being made.

Coincident with the message to Congress by the President came a message from the Committee on Economic Security to the President and the report that it submitted to the President. The committee, which includes as chairman Frances E. Perkins, Secretary of Labor, and Henry Morgenthau Jr., Secretary of the Treasury, Homer Cummings, Attorney General, H. A. Wallace, Secretary of Agriculture and Harry Hopkins, Federal Emergency Relief Administrator, indicates again in its report the difficulties inherent in a sickness insurance program but seems to forecast quite definitely its plans in relationship to this problem. Thus it says:

As a first measure for meeting the very serious problem of sickness in families with low income we recommend a nationwide preventive public health program. It should be largely financed by state and local governments and administered by state and local health departments, the federal government to contribute financial and technical aid. The program contemplates (1) grants in aid to be allocated through state departments of health to local areas unable to finance public health

programs from state and local resources, (2) direct aid to states in the development of state health services and the training of personnel for state and local health work, and (3) additional personnel in the United States Public Health Service to investigate health problems of interstate or national concern.

The second major step we believe to be the application of the principles of insurance to this problem. We are not prepared at this time to make recommendations for a system of health insurance. We have enlisted the cooperation of advisory groups representing the medical and dental professions and hospital management in the development of a plan for health insurance which will be beneficial alike to the public and the professions concerned. We have asked these groups to complete their work by March 1, 1935 and expect to make a further report on this subject at that time or shortly thereafter. Elsewhere in our report we state principles on which our study of health insurance is proceeding which indicate clearly that we contemplate no action that will not be quite as much in the interests of the members of the professions concerned as of the families with low incomes.

The committee proceeds somewhat further along in its report to a brief consideration of so-called health insurance, which still more elaborately hints at what is contemplated. Apparently the technical advisory staff of the Committee on Economic Security has made studies of the compulsory sickness insurance plans already established abroad. It has considered the possibilities of voluntary insurance and rejected them, as well as the possibility of ordinary commercial insurance. It has already, it seems, prepared the basic principles for a tentative plan of insurance believed adequate for the needs of American citizens with small means and appropriate to existing conditions in the United States. These are said to have been submitted to the professional advisory groups organized for the purpose already described in *THE JOURNAL*, the advisory groups have requested an extension of time and the extension has been granted until March 1. The statement is made that "arrangements have been effected for close cooperative study between the committee's technical staff and the technical experts of the American Medical Association." In its report submitted to the President, the Committee on Economic Security offers the following information to the professions and to the public as to the main lines along which its studies are proceeding:

1 The fundamental goals of health insurance are (a) the provision of adequate health and medical services to the insured population and their families, (b) the development of a system whereby people are enabled to budget the costs of wage loss and of medical costs, (c) the assurance of reasonably adequate remuneration to medical practitioners and institutions, (d) the development under professional auspices of new incentives for improvement in the quality of medical services.

2 In the administration of the services the medical professions should be accorded responsibility for the control of professional personnel and procedures and for the maintenance and improvement of the quality of service, practitioners should have broad freedom to engage in insurance practice, to accept or reject patients, and to choose the procedure of remuneration for their services, insured persons should have freedom to choose their physicians and institutions, and the insurance plan shall recognize the continuance of the private practice of medicine and of the allied professions.

3 Health insurance shall exclude commercial or any other intermediary agents between the insured population and the professional agencies which serve them

4 The insurance benefits must be considered in two broad classes (a) cash payments in partial replacement of wage loss due to sickness and for maternity cases, and (b) health and medical services

5 The administration of cash payments should be designed along the same general lines as for unemployment insurance and, so far as may be practical, should be linked with the administration of unemployment benefits

6 The administration of health and medical services should be designed on a state-wide basis, under a federal law of a permissive character. The administrative provisions should be adapted to agricultural and sparsely settled areas as well as to industrial sections, through the use of alternative procedures in raising the funds and furnishing the services

7 The costs of cash payments to serve in partial replacement of wage loss are estimated as from 1 to 15 per cent of pay roll.

8 The costs of health and medical services, under health insurance, for the employed population with family earnings up to \$3,000 a year, is not primarily a problem of finding new funds but of budgeting present expenditures, so that each family or worker carries an average risk rather than an uncertain risk. The population to be covered is accustomed to expend, on the average, about 45 per cent of its income for medical care.

9 Existing health and medical services provided by public funds for certain diseases or for entire populations should be correlated with the services required under the contributory plan of health insurance.

10 Health and medical services for persons without income, now mainly provided by public funds, could be absorbed into a contributory insurance system through the payment by relief or other public agencies of adjusted contributions for these classes.

11 The role of the federal government is conceived to be principally (a) to establish minimum standards for health insurance practice and (b) to provide subsidies, grants or other financial aids or incentives to states which undertake the development of health insurance systems which meet the federal standards

Promptly on the submission of these messages and reports to the Congress of the United States, Senator Wagner of New York submitted in the Senate S 1130, which is known as the Wagner Bill for Social Insurance. It covers specifically old age assistance, aid to dependent children, earnings and employment excise taxes. It sets up a social insurance board composed of three persons appointed by the President, to be a part of the Department of Labor. This board is authorized, with the approval of the Secretary of Labor, to appoint and fix compensation of all officers, attorneys and experts needed, without regard to civil service laws. Under this board will come the control of old age insurance, unemployment compensation, accident compensation, health insurance and related subjects. Annuity certificates and taxes on payrolls of 3 per cent are provided as means of raising funds.

Under the heading maternity and child welfare, this bill appropriates \$4,000,000 annually to enable the federal government to cooperate with the state agencies of health in extending and strengthening services for the health of mothers and children, especially in rural areas

and in areas suffering from severe economic distress. This is to be administered by the Department of Labor. Each state is to get \$20,000 annually, and \$1,000,000 is to be apportioned among states in proportion to the respective live birth rates. The Secretary of Labor may apportion \$800,000 among states that are unable to match the federal appropriation. Furthermore, the Secretary of Labor may use the remainder to make special demonstrations and conduct research in maternal care. To secure the federal funds, the states must submit their plans to the Children's Bureau and obtain approval.

For the care of crippled children the Wagner bill provides \$3,000,000 annually, to be handled in much the same way as the funds for maternal and child welfare are to be handled, also subject to approval of the Children's Bureau.

For child welfare services \$1,500,000 annually is allotted, also distributed and controlled along the same lines.

Finally, the Wagner bill appropriates \$10,000,000 annually to be administered by the Bureau of the Public Health Service. The bureau is to allot \$8,000,000 to the states in amounts determined on the basis of the need of each state for such assistance, to develop state health services, including the training of personnel for state and local health work and for the purpose of assisting counties or other political subdivisions of the states in maintaining public health programs. The sum of \$2,000,000 is to be made available annually to the Public Health Service for the further investigations of diseases and problems of sanitation and related matters.

This, then, is the outline of plans by the federal government for immediate action in relationship to economic security, and also a general outline of what may be anticipated in the way of a system of sickness insurance to be proposed about March 1. It is understood that the Wagner bill is to be a first order of business with the Congress now in session. *THE JOURNAL* has repeatedly called attention to the political situation, which indicates that any measure proposed by the administration is likely to have legislative approval and to pass speedily into the law of the land.

Physicians will recognize in the plans for maternal and child welfare, and for the care of the crippled, a repetition of the methods operative under the Sheppard-Towner law, except that the money now to be made available is somewhat in excess of what was then used for these purposes.

The work of the United States Public Health Service is worthy of generous support. The amount of money now spent for preventive medicine is insignificant compared to the total budget of the nation for medical purposes.

Readers of *THE JOURNAL* need not be reminded of the various criticisms that have been brought against the use of federal subsidies to the individual states to

induce legislation by the states. Essentially this provides federal control, because all plans for expenditure must be approved by a federal bureau before the appropriation can be secured. Moreover, the states that fail to cooperate merely deprive themselves in order to make more money available to other states. Finally, most of this important medical work is placed in the Department of Labor, under what is essentially non-medical control, instead of being correlated under the United States Public Health Service. Again and again, plans have been suggested for gathering together the medical services of the federal government under some single leadership of a medical character, yet these services remain distributed through the Department of the Interior, the Department of Labor, the Department of Agriculture, the Treasury and others. Now it is proposed that the Social Insurance Board shall undertake still other responsibilities, some of which inherently involve medical considerations. Fortunately, all concerned realize the complex character of the problems to be approached and all seem willing to undertake these projects in an experimental manner, subject to such revisions and modifications as may be necessary.

The point of view of the American Medical Association is apparently clear to the Committee on Economic Security. It is the only nongovernmental organization specifically mentioned by name in the Report of the Committee on Economic Security. Moreover, the eleven broad principles outlined by the committee as fundamental to the design of a sound plan of health insurance reflect distinctly the ten principles to control experiments in medical practice adopted by the House of Delegates of the American Medical Association at its meeting in Cleveland last June. Here is recognition of the importance of sustaining the quality of medical service, professional responsibility in administering medical care, free choice of physician and institution, continuance of private practice, exclusion of commercial intermediary agents, state rather than federal control, and other minor factors.

In submitting its eleven principles, may we again point out, the Committee on Economic Security says:

From the very outset, however, our committee and its staff have recognized that the successful operation of any such plan will depend in large measure upon the provision of sound relations between the insured population and the professional practitioners or institutions furnishing medical services under the insurance plan.

The committee states that it has already submitted this tentative plan to the various professional advisory groups organized for this purpose and it is announced that these advisers will not report until March 1. Time is therefore now available in which the medical profession as a whole as represented by the American Medical Association, and in smaller units as represented by state and county medical societies, may make its views clear both to the appropriate advisory committees and to the Committee on Economic Security. The American Medical Association has opportunity to pre-

sent its attitude to these bodies and, indeed, to Congress itself, when eventually legislation is promulgated to make the views of the committee a part of the national administration of our lives.

THE JOURNAL has emphasized repeatedly that no system of medical practice can succeed unless the medical profession gives it whole-hearted support and cooperation. Physicians everywhere must make themselves fully conversant with the trend of the legislation that is proposed so that they may, in turn, enlighten the senators and representatives who speak for them in Congress. We seem to have impressed considerably with our point of view those who are undertaking the development of these new experiments in the conduct of medical care. We must not lose heart. Convinced of the righteousness of our attitude, knowing that the medical profession alone understands the fundamental human factors at the basis of the best medical care, it is our duty to do our utmost to make our point of view prevail. This we must do not only for economic security but also to secure to the American people a continuance of the high quality of medical care that has been theirs up to now.

DIET AND RELIEF

In the establishment of various relief bodies, much consideration has been given to the development of relief rations suitable to the people to whom they are distributed. It has long been known that there are racial differences as well as national habits in relation to food consumption. Indeed, as was pointed out by Dr. Lafayette B. Mendel¹ before the annual session of the American Medical Association in 1932, definite epochs exist in the evolution of diet. Diets change not only through the introduction of new food substances but also as a result of changing habits and methods of work. In association with the development of motor cars and the introduction of many machines into industry there has been a lessening consumption of carbohydrates. In this connection the story of sugar is of especial interest. In 1823 its annual consumption was 8.8 pounds per person, in 1931 it was 108 pounds, and today it is from 99 to 100 pounds. Such a change in food habits is vitally significant to the industry involved in the production of food. Furthermore, the sophistication of food substances in their manufacture has tended to deprive them more and more of such essential substances as the vitamins and the mineral salts, which, it is realized today, are highly significant for health.

In the provision of any diet it is necessary, if one would have the food consumed by those who require it, to consider not only the essentials such as proper proportions of protein, carbohydrates and fats, mineral salts and vitamins but also those factors of racial taste

¹ Mendel, L. B. The Changing Diet of the American People. J. A. M. A. 99: 117 (July 9) 1932.

and preference which have so much to do with the creation or loss of appetite. A study of the foods consumed by people who eat at restaurants in which one can have all one wants of anything on the menu for a fixed price brought out the amazing information that there was less and less choice of heavy foods and more and more of desserts such as ice cream cake and chocolate eclairs. Experts in the field of nutrition have pointed out repeatedly that it is unsafe to trust the individual to the guidance of the appetite alone, even though some evidence with lower animals indicates that they will satisfy their appetites and at the same time obtain suitable nutrition. Babies and the lower animals are not guided as are adult human beings by what is rather flatteringly called human intellect.

Thus it has been necessary for relief organizations in preparing rations of food for various families to work out lists that will appeal to various racial and national groups. Since there are many different groups in the United States, the Illinois commission found it expedient to develop four standard dietaries, planned for seven persons in a family, and to emphasize to these people the desirability of adding fruits, vegetables, eggs and milk to the materials supplied by relief commissions. The four dietaries are listed as general, southern, Italian and Jewish dietaries. The cereal products in these selections include, for example, spaghetti for all the groups, eliminate macaroni from the southern and Jewish groups, and include extra amounts of macaroni and vermicelli for the Italian group. For example, the general, southern and Jewish lists provide 2 pounds of spaghetti per month, whereas the Italian list includes 15 pounds of spaghetti per month. The general diet provides rather large quantities of navy beans, which are eliminated from the southern diet. The Jewish list fails to include pork and beans but does include four cans of sardines to three in the Italian and general lists and two in the southern list. The southern list includes 4 pounds of salt pork, which is entirely eliminated from the other three lists.

Such considerations are of the greatest importance for physicians who are concerned with the provision of suitable food for the sick. Nutritional benefit, as has been pointed out by H. C. Sherman, comes from what we eat rather than from lists of what we should eat. Money spent for food that is not eaten represents a serious wastage, particularly in a period when economic considerations must dominate many others. Furthermore, the rapid advancement of our knowledge has given opportunity to exploitation by the charlatan and the commercially minded who do not hesitate to abuse the truth in their promotions. The application by scientific medicine of the nutritional knowledge now already available has done much to improve health. The opportunities for the future are limited only by the possible increase of knowledge and the extent of its application.

Current Comment

METASTASES FROM THYROID TUMORS

When malignant thyroid tumors metastasize in distant and unexpected locations, the cells of the primary tumor have usually invaded the blood vessels and have thus been disseminated in the blood stream. In a study of 124 cases of metastatic lesions, Dinsmore and Hicken¹ found that (except for the cervical lymph nodes) the most common site of metastases was the lungs, and next the bones. The theory that the development of the transported cells into large metastatic tumors depends on a correct affinity between the cancer cells and the organ where they lodge would seem to explain the tendency of epithelial tumors of the thyroid to metastasize to bones. It is evident that metastases occur more frequently where the red bone is found, in the skull, vertebrae, pelvic bones, ribs and the proximal end of the humerus and femur. The highly nutritive bone marrow may encourage the growth of the metastatic tumor until it destroys the adjacent bone by pressure and thus produces a pathologic fracture or even invades the soft tissues adjacent to the bone and finally ulcerates through the skin. The first sign of a primary thyroid tumor may be a metastatic tumor in some bone. In such cases the primary tumor may be so small that it can be recognized only by a histologic examination of the metastases in the bone. The unusual sites of metastases of thyroid tumors are the liver, kidneys, brain, heart, and soft tissues of the orbit of the eyes. The concept of the "benign metastasizing goiter," which was encouraged by Cohnheim's case reported in 1876 and in which some still believe, is confusing and should be abandoned. This interesting study, made at the Cleveland Clinic, shows further that accurate diagnosis requires an ever increasing breadth of knowledge.

RETENTION OF MANGANESE

One of the newer points of interest in nutrition pertains to the physiologic importance of chemical elements that are unusual because they occur in the diet in extremely small amounts. Certain of these, notably iodine and iron, are known to be constituents of compounds essential to the normal function of the body, copper and perhaps other metals appear to be concerned rather with certain metabolic processes. Among the latter group, manganese has received considerable attention. Elimination of this element from an otherwise adequate experimental ration has been shown to produce sterility in the male and interference with normal lactation in the female. At birth the concentration of manganese is higher than at any time later, indicating an accumulation in fetal tissues during intra-uterine development. Whereas the amount stored in the tissues can be increased by feeding this element, none was found in the organs of experimental animals consuming a manganese-free ration. Information regarding the biochemical significance of this metal has been extended to human subjects in a recent study by Ever-

¹ Dinsmore, R. S. and Hicken, N. F. Metastases from Malignant Tumors of the Thyroid. *Am. J. Surg.* 24:202 (May) 1934.

son and Daniels¹ Determinations of the retention of manganese in three girls and four boys ranging in age from 3 to 5 years were made over ten day periods while three adequate diets differing only with respect to the content of manganese were being consumed. It was observed that the excretion of the metal in the urine was extremely low. A large part of the manganese was lost in the feces the proportion varying from 80 to 90 per cent of the amount consumed. With daily intakes of 0.113, 0.158 and 0.307 mg per kilogram of body weight the retention was 0.01, 0.031 and 0.059 mg per kilogram of body weight respectively. Assuming that the maximum retention is optimal, the conclusion is reached on the basis of the Iowa study that the diet of children should contain from 0.2 to 0.3 mg of manganese per kilogram daily. Despite the inevitable limitations to interpretation, these observations provide additional data regarding one aspect of nutrition that is attracting increasing attention.

Medical Economics

RECENT BRITISH HEALTH INSURANCE COSTS

The Fifteenth Annual Report of the Ministry of Health of Great Britain covering the fiscal years 1933 and 1934, supplies some interesting facts concerning the workings of the British health insurance system.

"The number of insured persons entitled to medical benefits was approximately 15,150,000." There were 15,500 doctors in insurance practice. About 10,000 druggists supplied medicines and appliances. The total cost of medical benefit was £8,420,000 (\$42,100,000).¹ These figures show that the average expenditure for medical relief was \$2.77 per person annually.

The physicians received for attending and treating insured persons, £6,077,000 (\$30,385,000). According to these figures, insurance physicians received close to \$2 per person annually.

In spite of all the restrictions and denunciations of over-medication, the report says:

"There was an increase of nearly 6 per cent in the number of insurance prescriptions dispensed in 1933 as compared with 1932, the numbers rising from 56,081,507 to 59,338,504 and the average number of prescriptions issued per insured person entitled to supplies increased from 4.19 to 4.56.

"The total of the chemists' accounts rose from £1,865,123 (\$9,325,615) (in 1932) to £1,985,885 (\$9,929,425) (in 1933, representing \$0.65 per insured person) and the following movements in the cost of the service also occurred:

	1932	1933
Average ingredient cost (in pence) per prescription	3.594d (\$0.0718)	3.643d (\$0.0728)
Average total cost of drugs and prescribed appliances per insured person entitled to obtain them from chemists	2s 9½d (\$0.67)	2s 11½d (\$0.71)

"The above increases were mainly due to the prevalence of influenza during the earlier months of the year."

In addition to these sums a little over \$1,000,000 was paid for mileage. The physicians received directly for services approximately \$2,000 a year, out of which they were required to pay all their expenses except mileage as noted. Some of them dispensed their own medicines which accounted for about \$900,000 more. Since the mileage and the payments for medicines cover little more than out-of-pocket expenses, the actual gross income remains about \$2,000 annually, out of which all other expenses of practice must be paid.

To be sure, this is not the total income received by the physicians, since the great majority of them had some private practice. The fees for that practice, however, tend to be fixed in most localities at very low rates, owing to the standards set up by the insurance system. Although £9,000 (\$45,000) "was set aside to enable country doctors to attend courses of postgraduate study," only £2,830 (\$14,150) of this was expended. This "enabled 102 doctors to attend short courses of postgraduate study."

Much has been made of the fact that the proposal to abolish regional medical officers was objected to by the insurance practitioners because, it was claimed, these officers were available for consultation purposes. The report shows that only 1,472 'consultation' references were received, 1,443 from societies and 29 from insurance doctors. There has been a continual decline in the number of such references from insurance doctors and these figures would seem to indicate that the number of such consultations was close to the vanishing point.

"The total number of references for advice as to incapacity for work in 1933 was 503,254 (500,769 from Approved Societies, and 2,485 from insurance doctors). Of these references 202,514 (or 40 per cent) related to men, and 300,740 (or 60 per cent) related to women.

"The number of persons actually examined on 'incapacity' references was 268,157. The number who were reported to have received a final certificate before the date fixed for examination was 139,170, and 94,127 others did not attend for examination. Of the persons examined, 188,693 were reported as incapable and 79,464 as not incapable of work."

These figures continue to be a startling commentary on the difficulties of certification. The fact that over half a million such references are made annually in spite of all the regulations and cautionings that have been issued to restrict overcertification seems to be of considerable significance.

The largest single expenditure is still that for cash sickness benefits, which amounted to £9,562,000 (\$47,810,000). To this should be added "disablement benefit," which "is practically a continuance of sickness benefit at a reduced rate" and which amounted in 1932-1933 to £5,095,000 (\$25,475,000). The total payments for cash benefits is therefore, according to these figures, £14,657,000 (\$73,285,000), about \$4.92 for each insured person.

Expenditures for Health Service

Service	Expenditure	Total
Public health		
Hospitals, sanatoriums, dispensaries etc.	£ 3 600 698	\$ 18 003 490
For tuberculosis	439 308	2 196,540
For venereal diseases		
For other diseases (diphtheria, smallpox, etc.)	3 356 044	16 780,220
General hospitals	3,244 895	16,224,475
Notification of disease general disinfection etc.	565 824	2 829 120

Some of the proposed sickness insurance laws in this country that are offering much higher cash benefits than are paid in the English system and yet have set aside a smaller proportion of the total resources for this purpose than for medical relief would appear to be courting financial disaster. The total benefits, both cash and medical, and including several unlisted minor expenditures, in 1933 amounted to £26,790,000 (\$133,950,000), or approximately \$8.92 for each person insured.

The total receipts were £31,946,000 (\$159,730,000). Of this, £22,020,000 (\$110,100,000) was received from contributions by the insured and their employers. The men pay approximately 9 cents and the women 8 cents weekly, or about \$4.50 for the men and \$4 for the women annually. This may well be contrasted with the assessments proposed by most of the plans of

¹ Everson G. J. and Daniels Amy L. J. Nutrition 8: 497 (Nov) 1934.

² The British pound has been uniformly calculated as \$5 the shilling as 24 cents and the penny as 2 cents unless otherwise stated.

2 McCleary, G. F. National Health Insurance London H. K. Lewis & Co. Ltd. 1932 p. 48.

sickness insurance now being urged in this country, which call for employee contributions of from \$0.20 to \$1.80 weekly

The cost of administration is given as \$4,764,000 (\$23,820,000) which is approximately 14.9 per cent of the total receipts of \$31,946,000 (\$159,730,000). This is two thirds as much as was expended for the payment of physicians and about one fourth of the total cost of medical service and drugs. However there is much doubt whether this includes a considerable number of expenditures that are performed by other government departments such as the post office, for example and it does not include many forms of contribution to the health care of insured persons by public and private bodies.

In fact, the expenditures for other forms of medical care are steadily increasing, as is shown by the foregoing table

Association News

SPECIAL MEETING OF THE HOUSE OF DELEGATES

At the request of the Board of Trustees, a special meeting of the House of Delegates has been called by the Speaker of the House, to meet in Chicago at 10 a. m., Feb 15 1935

THE ATLANTIC CITY SESSION

Hotel Reservations

Hotels in Atlantic City report that many reservations are now being received for the annual session, June 10-14. The local Committee on Hotels, through which all hotel reservations are arranged, will do everything possible to secure the type of accommodations desired. However, it is an obvious advantage to make early application, and as an aid to those expecting to attend the session, a special "Hotel Reservations" page appears in the advertising section (page 41). This lists the hotels of Atlantic City and gives a complete schedule of rates for the various kinds of service. A reservation coupon is also provided, and it is suggested that the form be filled out and mailed at once to insure a better choice of accommodations.

MEDICAL BROADCASTS

Columbia Broadcasting System

The American Medical Association broadcasts on a western network of the Columbia Broadcasting System each Thursday afternoon on the Educational Forum from 4:30 to 4:45, central standard time. The next three broadcasts will be delivered by Dr. W. W. Bauer. The titles will be as follows:

January 31 Thirty Six Thousand Deaths
February 7 Heart Diseases
February 14 Heart Valves

National Broadcasting Company

The American Medical Association broadcasts under the title "Your Health" on a Blue network of the National Broadcasting Company each Tuesday afternoon from 4 to 4:15, central standard time. The next three broadcasts will be as follows:

January 29 Organizing for Health Morris Fishbein M.D.
February 5 Pipes and a Pump W. W. Bauer M.D.
February 12 Rheumatism and Gout, Morris Fishbein M.D.

Special Medical Broadcast Program

The American Medical Association will broadcast on a special program arranged through the courtesy of the National Broadcasting Company over a network of stations beginning at 6 p. m., eastern standard time Monday February 18. The program will include music and three speakers from among physicians in attendance at the Annual Congress on Medical Education and Medical Licensure meeting in Chicago on that day. The speakers will be introduced by Dr. Morris Fishbein. The speakers and their topics are as follows:

Advancement of Medical Education Walter L. Biering M.D.
The Prolongation of Life Ray Lyman Wilbur M.D.
The Battle Against Tuberculosis Kendall Emerson M.D.

ANNUAL CONGRESS ON MEDICAL EDUCATION, HOSPITALS AND LICENSURE

Program of Meetings to be Held in Chicago,
February 18 and 19

The thirty-first Annual Congress of the Council on Medical Education and Hospitals of the American Medical Association will be held at the Palmer House, Chicago, February 18 and 19. The Federation of State Medical Boards of the United States will participate in the congress. The program follows:

MONDAY, FEBRUARY 18, 10 A. M.

RAY LYMAN WILBUR M.D. Presiding

Report of the Council on Medical Education and Hospitals
Ray Lyman Wilbur M.D. Chairman Stanford University Calif.
Should the Number of Professional Students Be Restricted?
Raymond Walters Litt D. President, University of Cincinnati
Discussion Olin West M.D. Chicago
The History of Medical Licensure
Henry E. Sigerist M.D. Director Institute of the History of Medicine Johns Hopkins University Baltimore
Discussion Irving S. Cutter M.D. Chicago
The Larger Social Aspects of Medical Education
Richard E. Scammon Ph.D. Dean of Medical Sciences University of Minnesota Medical School Minneapolis
Discussion Willard C. Rappleye M.D. New York.

Red Lacquer Room

MONDAY, FEBRUARY 18, 2 P. M.

FREDERIC A. WASHBURN M.D. Presiding

Tuberculosis Institutional and Educational Aspects

Objectives of the Campaign Against Tuberculosis
Kendall Emerson M.D., Managing Director National Tuberculosis Association New York
Discussion Henry C. Sweeney M.D. Chicago
Education of Physicians in Tuberculosis
James Alexander Miller M.D., Professor of Clinical Medicine Columbia University College of Physicians and Surgeons New York
Discussion James J. Waring M.D. Denver
Some Historical Aspects of Tuberculosis
L. J. Moorman M.D. Dean University of Oklahoma School of Medicine Oklahoma City
Discussion Kennon Dunham M.D. Cincinnati
Function of the General Hospital in the Treatment of Tuberculosis
J. A. Myers M.D. Professor of Medicine Preventive Medicine and Public Health University of Minnesota Minneapolis
Discussion Edward S. McSweeney M.D. New York.

Red Lacquer Room

TUESDAY, FEBRUARY 19, 9 A. M.

JOINT SESSION OF THE COUNCIL ON MEDICAL EDUCATION AND HOSPITALS AND THE FEDERATION OF STATE MEDICAL BOARDS

ROY B. HARRISON, M.D. Presiding

Should the Practice of Radiology, Pathology and the Administration of Anesthetics Be Limited to Those Who Are Licensed to Practice Medicine?

Legal Aspects
William C. Woodward M.D. Director Bureau of Legal Medicine and Legislation American Medical Association Chicago
Administrative Aspects
A. T. McCormack M.D., Secretary Kentucky State Board of Health Louisville
The Radiologist
B. R. Kirklin M.D. Mayo Clinic Rochester Minn.
The Pathologist
J. P. Simonds M.D. Professor of Pathology Northwestern University Medical School Chicago
The Anesthetist

Are Interns Practicing Medicine?

Harold Rypins M.D. Secretary New York Board of Medical Examiners Albany

Discussion J. W. Bowers M.D. Fort Wayne Ind

Uniform Standards in Licensure

Charles B. Pinkham M.D. Secretary California Board of Medical Examiners Sacramento

Discussion Arthur W. Booth M.D. Elmira N. Y.

EXECUTIVE SESSION FEDERATION OF STATE MEDICAL BOARDS

Red Lacquer Room

Federation Dinner

The annual dinner of the Federation of State Medical Boards of the United States will be held Monday at 6:30 at the Palmer House. All attending the congress are invited.

PROGRAM

Address by Henry E. Sigerist, M.D. Director Institute of the History of Medicine Johns Hopkins University Baltimore.

Presidential address of Henry M. Fitzhugh M.D. Secretary Maryland Board of Medical Examiners Baltimore

Round table conference

Reduced Railway Fares

Reduced railway fares will be in effect for those who attend the congress. In some cases excursion rates are offered. In most instances, however, the reduced rate will be upon the certificate plan. This certificate must be obtained at the point of departure at the time of purchase of the railroad ticket to Chicago and must be countersigned by a representative of the railroad at the congress in order to entitle the holder to a reduced fare on the return trip.

Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION, PUBLIC HEALTH, ETC.)

CALIFORNIA

Dr. Major Gives Scripps Lectures—Dr. Ralph H. Major, professor of medicine, University of Kansas School of Medicine, delivered the annual Scripps Metabolic Lectures, January 10-12, La Jolla. The subject was *Bedside Clinics*.

Personal—Dr. Alexander M. Lesem, director of public health of the city and county, has been chosen president of the newly organized San Diego Public Health Association.—Dr. John M. Wakefield, Sutter Creek, has been appointed health officer of Amador County, succeeding the late Dr. George L. Lynch.—Dr. Carlton C. Purviance has been named health officer of Fairfield, succeeding the late Dr. Henry V. Climer.

Bills Introduced—S. 21 proposes to regulate the production and distribution of serums, vaccines, bacterial cultures and viruses and to require the licensing by the department of public health of persons manufacturing, preparing and distributing such products. A. 8, to amend the workmen's compensation act, proposes to extend the benefits of the act to all persons performing services for any public body in return for aid or relief. A. 73 proposes to transfer to and vest in the state board of pharmacy all powers, duties and functions vested in the chief of the division of narcotic enforcement.

Popular Medical Lectures—James M. D. Olmsted, Ph.D., gave the first of the annual series of popular medical lectures sponsored by Stanford University School of Medicine, San Francisco, in Lane Hall, January 4. His subject was "Brain Activities." Dr. Harold K. Faber gave the second in the series, January 18, on "Poliomyelitis." Other lectures will be:

Dr. Maurice L. Tainter, February 1, *Dinitrophenol in the Control of Obesity*.

Nathan Van Patten, director of university libraries, February 15, *Quinine: The First Hundred Years*.

Dr. William P. Shepard, March 1, *Present Day Relationships Between Medicine and Industry*.

Dr. Mary H. Lavman, March 15, *Growth and Development in Infancy*.

Course in Ophthalmology and Otolaryngology—The fourth annual midwinter clinical course in ophthalmology and otolaryngology, given by the Research Study Club of Los Angeles, opened January 21 and will continue until February 2. At a dinner meeting, January 28, of the Los Angeles County Medical Association and the Research Study Club, the speakers will be Prof. Georges Portmann, professor of otorhinolaryngology, University of Bordeaux, Faculty of Medicine, France; Drs. John

T. Barnhill, professor of surgery of the head, Indiana University School of Medicine, Indianapolis; Harry S. Gradle, professor (extramural) of ophthalmology, Northwestern University Medical School, Chicago; and Webb W. Weeks, professor of ophthalmology, New York University, University and Bellevue Hospital Medical College.

CONNECTICUT

Dr. Winternitz Resigns as Dean—Dr. Bayne Jones, Appointed—Dr. Milton C. Winternitz, whose term of office as dean of the Yale School of Medicine expires in June, has declined to be considered for reappointment; it was announced, January 15. Dr. Stanhope Bayne-Jones, professor of bacteriology at the school since 1932, has been named to succeed Dr. Winternitz for a period of five years beginning July 1. Dr. Winternitz has been teaching at Yale since 1917, first as professor of pathology and bacteriology and later as Anthony N. Brady professor of pathology, and has been dean since 1920. He will continue as professor of pathology. Dr. Bayne-Jones received his medical degree from Johns Hopkins University School of Medicine in 1914, having previously graduated from Yale. During the World War he served as medical officer with the British Expeditionary Forces for ten months, later was with the Twenty-Sixth Division of the American Expeditionary Forces, and finally with the rank of major was sanitary inspector of the Army of Occupation receiving the British military cross and the *croix de guerre*. From 1919 to 1923 he was associate professor of bacteriology at Johns Hopkins and for the next eight years was professor of bacteriology at the University of Rochester (N. Y.). While in Rochester he was also director of the Rochester Health Bureau Laboratories. On leave from Yale in 1932 and 1933, he was chairman for one year of the Medical Science Division of the National Research Council in Washington. Since 1931 he has been a member of the Council on Pharmacy and Chemistry of the American Medical Association. He is a former president of the Society of American Bacteriologists and of the American Association of Immunologists. Recently he was elected vice president for Section N of the American Association for the Advancement of Science. He is the author of many publications in his field. At Yale he is master of Trumbull College, one of the seven student houses.

DISTRICT OF COLUMBIA

Medical Bills in Congress—S. 368, introduced by Senator Capper, Kansas, and Senator Copeland, New York, and H. R. 4135, introduced by Representative Norton, New Jersey, propose to amend the Code of Laws for the District of Columbia to provide relief, aid, care and support for the aged.

Society News—Dr. Arthur H. Ruggles, Providence, R. I., among others, addressed the annual dinner meeting of the Washington Institute of Mental Hygiene, Dec. 7, 1934, on "Mental Hygiene and Education."—Dr. William Charles White was reelected president of the District Tuberculosis Association, Dec. 21, 1934.

ILLINOIS

Society News—Dr. John D. Camp, Rochester, Minn., addressed the Peoria City Medical Society, January 22, on "Significant Roentgenologic Changes in the Spine," and January 15 the speaker was Dr. George E. Shambaugh, Jr., Chicago, on "What Can Be Done for Sinus Disease?" Dr. George W. Parker was recently elected president of the society.—The La Salle County Medical Society was addressed at La Salle, January 10, by Drs. Italo F. Volini, Chicago, on "Etiologic Diagnosis of Heart Disease," and Robert A. Black, Chicago, "The Rheumatic Heart in Children."—Dr. Theodore N. Rafferty, Robinson, addressed the Crawford County Medical Society in Robinson, January 10, on "Intra-Abdominal Hemorrhage of Ovarian Origin."

Four Year Study of Accidents—In a recent report of accidents in Illinois for the four years 1930-1933 released by the state department of health, it was stated that accidents account for one in every seven deaths in some counties, while in others only one in twenty-five fatalities is attributed to accidents. For this period accidents were responsible for 23,905 deaths in Illinois, and of these 8,938 were charged to motor vehicle mishaps. For all accidents the highest rates prevailed in Alexander, Union, Christian, Morgan and Lake counties, in the order named, where the number of deaths ranged from 140 to 120 per hundred thousand of population. The most favorable rates prevailed in Menard, Pratt, Jasper, Wayne and Moultrie counties where the annual losses averaged from 36 to 40 per hundred thousand of population. For motor vehicles alone Lake County had the worst record by a wide margin, 60 deaths per

hundred thousand annually from automobile mishaps. Next in order were Edgar, with a rate of 49, DeKalb, 43, Will, 42, McLean, 41, Grundy, 40, and Kankakee, 40. Calhoun County was the only one in which no death was attributed to motor vehicles. The state at large had an average loss of 77 per hundred thousand from all accidents for the four years.

Chicago

Dr Greenough Gives McArthur Lecture—Dr Robert B. Greenough, Boston, will deliver the eleventh Lewis Linn McArthur Lecture of the Frank Billings Foundation of the Institute of Medicine, February 22. His subject will be "Cancer Education in Medical Schools."

Hospital News—Cook County Hospital cared for 70,427 patients during the fiscal year ended December 1, an increase of 153 over the number hospitalized in 1933. The daily average is 2,680 patients for 1934 as compared with 2,652 during 1933, according to the *Chicago Tribune*.—Prof Ulrich Friedemann of the staff of the British National Research Council lectured at the Albert Merritt Billings Memorial Hospital on "Experimental Investigation on the Blood-Brain Barrier in Infectious Diseases."

Society News.—Dr Ludwig Fraenkel, professor and head of the department of gynecology and obstetrics, University of Breslau, Germany, gave an illustrated lecture before the Institute of Medicine of Chicago and the Chicago Gynecological Society, January 15, his subject was "Etiology, Diagnosis and Treatment of Parametritis."—Speakers before the Chicago Society of Internal Medicine, January 28, will be Dr William S. Hoffman on "Relation of Serum Inorganic Sulphate to Renal Efficiency," Dr Franklin C. McLean and Albert Baird Hastings, Ph.D., "Clinical Observation of the Calcium Ion Concentration in the Blood," and Dr Géza de Takáts, "Observations on Buerger's Disease."

KANSAS

Bills Introduced—H 55 and H 56 propose to authorize the licensing of dental hygienists by the board of dental examiners. Such licentiates are to be permitted to remove calcic deposits, accretions and stains from the surfaces of the teeth but are not to perform any other operation on the teeth or tissues of the mouth. A dental hygienist is to be permitted to operate only under the general direction or supervision of a licensed dentist, in his office or in any public school or other institution. S 63 proposes (1) to require each party to a proposed marriage, as a condition precedent to obtaining a license to marry, to present a certificate from a licensed physician that he or she is free from mental and venereal disease, (2) to limit to \$3 a physician's fee for examining each party, and (3) to provide that no license shall issue when either party is epileptic, feeble-minded, idiotic, insane, or has any venereal disease.

MARYLAND

Society News—A joint meeting of the Baltimore City Medical Society and the Mid-Atlantic Urological Society, January 18, was addressed by Drs Howard A. Kelly, Baltimore, on "Radium Treatment of Bladder Tumors Benign and Malignant", Ray M. Bobbitt, Huntington, W. Va. on "Experiences in Prostatic Resection in Carcinoma of the Prostate", Harry A. Fowler, Washington, D. C., "Pseudomembranous Trigonitis What Is It? What Can We Do for It?", Benjamin S. Abeshouse, Baltimore, "Gastro-Intestinal Symptoms in Diseases of the Upper Urinary Tract, the So-Called Retroperitoneal Syndrome," and Horatio N. Dorman, Washington, D. C., "Necrosis of the Testicle Following Bladder Neck Surgery."—At a meeting of the Osler Historical Society, Baltimore, January 15, Dr Jesse W. Downey Jr, Baltimore, presented "Brief Notes on the Ear in Medical History, with an Exhibition of Some of the Earliest Textbooks on Otology," and Dr David I. Macht, "A Pharmacological Appreciation of Shakespeare's Romeo and Juliet."—Dr Victor F. Cullen, State Sanatorium, discussed "Late Developments in Tuberculosis" before the Allegany-Garrett Counties Medical Society in Cumberland, Dec. 14, 1934.—The Baltimore County Medical Association was addressed, Nov. 21, 1934, by Dr Perrin H. Long on the common cold.—Dr Alan C. Woods, Baltimore, addressed the Frederick County Medical Society, Nov. 20, 1934 on "Ocular Tuberculosis, Its Diagnosis and Treatment."

University Hospital Dedicated—The dedication of the University Hospital of the University of Maryland, Baltimore took place, Dec. 15, 1934. Dr Irving S. Cutter dean, Northwestern University School of Medicine Chicago, gave the dedicatory address. Other speakers included Albert C. Ritchie

then governor of Maryland, and Dr Alan M. Chesney, dean of Johns Hopkins University School of Medicine. Located at Redwood and Greene streets, the building is ten stories high, with the center portion carried up into a tower to provide five extra floors. The exterior of the structure is plain brick. Purchased steam heats the building, doing away with the necessity of a boiler plant. The building is in the shape of a cross with wings radiating in four directions from a common center, providing a means of communication up through the center, without transgressing any department and yet readily accessible to all departments. It also provides for a separation between the teaching wards and pay wards and still gives each department its own floor or portion to itself. An unusual feature is that practically all the specialized treatment service has been concentrated on one floor, the second. The arrangement of the space from the second floor to the eighth has been designed for teaching, while the ninth and tenth floors have been set aside for private and semiprivate pay patients. One section of the floors for obstetric and pediatric patients has been reserved for those who require special services. Of the 394 beds in the new hospital seventy-one are for private patients,

The new University Hospital

sixty-five for semi-private and 258 for ward patients. About \$1,500,000 was allocated in 1932 by the general assembly to erect the building. The old University Hospital was built in 1896, although the institution itself was established in 1823. This structure, which provides 250 beds, forty-five of which are devoted to Negro patients, will be remodeled and used for a general outpatient department.

MASSACHUSETTS

Bills Introduced—H. 713, to amend the workmen's compensation act, proposes to limit the medical and surgical aid to an injured employee for which the employer is liable to a period of two weeks immediately following the injury. Under the present law the employer must render such aid for the first two weeks after the injury, but, if the employee is not immediately incapacitated thereby from earning full wages, the time of such liability on the part of the employer dates from the beginning of the incapacity. H. 755 proposes to provide (1) that no person shall be required to submit to any form of vaccination or inoculation unless the physician supplies a written guaranty of the purity of the virus to be used, and (2) that any physician vaccinating a child, without the consent of the parents or guardians, or an adult without his consent shall be personally liable for all injuries resulting therefrom. H. 768 proposes to provide for the establishing under the state department of health of a system of clinics to which persons arrested for intoxication may be committed for treatment.

MICHIGAN

Bill Introduced—S. 45, to amend the workmen's compensation act, proposes to make compensable any incapacity or disability arising out of and in the course of any employment covered by the act. This would bring under the coverage of the act all manner of disease and injuries, whether accidental or otherwise.

Dr Barker to Give Beaumont Lectures—Dr Lewellys F Barker, professor emeritus of medicine, Johns Hopkins University School of Medicine, Baltimore, will deliver the Beaumont Lectures of the Wayne County Medical Society, Detroit, February 4-5, on "Heredity and Environment in Relation to the Handicapped." The subtitle of his first lecture will be "The Origin and Nature of Human Handicaps" and the second "The Amelioration of the Condition of the Handicapped and the Possibilities of Reduction of Their Numbers by Modification of Heredity and Environment." Dr Barker will address the students of Wayne University Medical School the morning of February 5, on "Major and Minor Medical Morals."

Dr Furstenberg Appointed Dean—Dr Albert C Furstenberg, professor of otolaryngology, University of Michigan Medical School, Ann Arbor, has been appointed dean to succeed Dr Frederick G Novy, who recently resigned. Dr Furstenberg graduated from the University of Michigan in 1915. Since his internship he has been a member of the faculty of his alma mater in various capacities until his appointment in 1932 as professor and head of the department of otolaryngology. It was simultaneously announced that a division of health sciences had been created to serve as an advisory unit to the university. It will include the medical school, school of dentistry, division of hygiene and public health, school of nursing college of pharmacy and department of postgraduate medicine. Dr James D Bruce, vice president of the university and head of the department of postgraduate medicine, has been named chairman of the newly created division. Both appointments are effective with the beginning of the second semester, February 9. The appointment of an executive committee was also announced. Dr Furstenberg, chairman, Dr Harley A Haynes, director of the university hospital, Dr Bruce, Dr Frederick A Collier, director of the department of surgery, Dr Carl V Weller, professor of pathology, and Dr Udo J Wile, professor of dermatology.

MINNESOTA

Bill Introduced—H 7 proposes to make it unlawful for any person to raise marijuana or prepare or manufacture marijuana into any product usable for smoking purposes.

NEW YORK

Coordination of Medical Society Activities—The council of the Medical Society of the State of New York, at a meeting Dec. 13, 1934, adopted resolutions authorizing the formation of special committees in the district branches of the society to study the objectives of various organized groups that exist within organized medicine. These committees are to endeavor to coordinate the efforts of members of the organized profession along parallel lines within the framework of the ten-point program of the American Medical Association. If and when any common ground is found and a conclusion reached, the committee is to report to the public relations committee of the state society, which may hold further hearings at its discretion and report to the council, the executive committee or to the house of delegates. If reports of the district committees are not in accord the public relations committee is to confer with the committees with a view to finding common ground between them.

Bills Introduced—S 123, A 150 and A 210 propose apparently to do away with the right which both the employee and the insurance carrier now have of selecting physicians at their own expense to participate in such physical examinations of the employee as may be required by the industrial board or by the industrial commissioner. A 185, to amend the medical practice act, proposes to make it unlawful for any one other than a licensed physician to conduct, direct, supervise or control the work or reports of a clinical laboratory, which is defined as a laboratory in which tests are made on individual persons, their secretions, excretions, blood and tissues to aid in the diagnosis, prognosis or treatment of the individual's physical or mental state or states. The provisions of this bill, however, are not to apply to qualitative or quantitative analysis of urine by a licensed pharmacist nor to a clinical laboratory director duly licensed to conduct, direct or supervise a clinical laboratory within the city of New York, nor to any person who has conducted, directed or supervised a clinical laboratory in the state for a period at least six months prior to the date this bill may become enacted. A 195 proposes to amend that provision in the vital statistics law which requires that the personal particulars called for in a certificate of birth shall be authenticated by the signature of an informant, who may be any competent person acquainted with the facts by provid-

ing that such personal particulars shall be obtained from a competent person acquainted with the facts. S 208 proposes to accord to physicians, nurses and hospitals, treating persons injured through the negligence of another liens on all judgments, settlements or compromises accruing to such injured persons by reason of their injuries.

New York City

Society News—Dr Charles H Hochman addressed the Bronx Pathological Society, January 15, on "Traumatic Rupture of the Brain Stem as a Cause of Sudden Death"—Drs Eli H Rubin and Theodore J Curphey addressed the Bronx County Medical Society, January 16, on "Modern Treatment of Pulmonary Tuberculosis" and "Recent Advances in Diagnosis and Treatment of Pneumonia," respectively.

Lectures in Bronx County—The winter session of lectures sponsored by the Bronx County Medical Society at Bronx hospitals has been announced as follows:

January 21, Dr Solomon Bilson Diabetes in the Young

February 4 Dr Milton J Goodfriend Uterine Bleeding in the Last Trimester

February 11, Dr Joseph Golomb Practical Points in Handling Children

February 18 Dr Henry Roth Minor Surgery

Special Study of Osteomyelitis—The Hospital for Joint Diseases announces that it is making a special study of the maggot treatment of osteomyelitis, for which patients living in or near New York may be referred for observation and treatment. Physicians who wish to refer bed patients are asked to telephone the hospital for reservations, ambulatory patients should be sent to the outpatient department Monday, Wednesday and Friday mornings.

Hospital Closes for Lack of Funds—St. Mary's Hospital for Children, established in 1870, closed its doors Dec. 31, 1934, because of insufficient income. Plans are now in the making to reopen the institution in the spring as a convalescent hospital for children. The hospital formerly operated two convalescent homes at Norwalk, Conn., and Peekskill, N. Y., but both have recently been closed for lack of funds. Last year 65.8 per cent of the ward services and 79.2 per cent of the outpatient department services were rendered free. This is the second hospital in New York to close within a month, the first having been the New York Nursery and Child's Hospital, founded in 1823.

Diabetes Association Formed—The New York Diabetes Association has recently been formed in affiliation with the New York Tuberculosis and Health Association to carry on a campaign against the disease, to be financed by a special contribution of \$15,000 made by Lucius N Littauer. The new organization will act as a clearing house for the study of diabetes as a health problem, devise measures for its control, assist in the formation of an association of clinics dealing with diabetes, develop graduate instruction for physicians, carry on health education of the general public in matters relating to diabetes, and obtain the provision of insulin for indigent sufferers and nursing service and hospitalization for all who require it. In its council will be included representatives of the tuberculosis and health associations, New York Academy of Medicine, city departments of health and hospitals, the five county medical societies, the schools of medicine, public and private hospital authorities, social and welfare agencies and interested laymen. Mr Littauer, a manufacturer, has previously contributed large amounts for support of public health activities, notably gifts of \$50,000 to Albany Medical College and \$10,000 to New York University for studies on pneumonia.

NORTH CAROLINA

Society News—Dr Carl V Reynolds, Asheville, acting state health officer, was guest of honor at a dinner given by the Buncombe County Medical Society at Asheville, Dec. 22, 1934. Dr Julian A Moore was toastmaster and talks were made by Drs Paul P McCann, Sanatorium, president, Paul H Ringer, Asheville, president-elect, and Louis B McBraver, Southern Pines, secretary of the Medical Society of North Carolina. Other speakers included Drs Charles H Cocke, Gibbons W Murphy, Clyde E Cotton, Joseph B Greene, Gaillard S Tennent and Dr Reynolds, all of Asheville. About forty physicians attended.

OKLAHOMA

Bill Introduced—S 14 proposes to authorize the sexual sterilization of habitual criminals and define as an habitual criminal any person convicted to final judgment three times for the commission of felonies.

PENNSYLVANIA

State's Hospitals Gave Sixty Per Cent Free Care in 1933—In 124 Pennsylvania hospitals, 60 per cent of the 5,468,048 days of care given to patients in 1933 was free, according to a study recently made public by the Hospital Association of Pennsylvania. The bed capacity of the hospitals was 25,747 and the average cost per day of the 3,284,096 free days was \$3.75. The association estimated that if the same ratio of free to paid service existed in the remaining 297 hospitals and sanatoriums in the state, excluding public hospitals, the total cost of free care would have been about \$28,000,000. Outpatient or dispensary service maintained by 202 hospitals cost an additional \$3,187,464. These estimates do not include overhead charges or any evaluation of physicians' services.

Philadelphia

Medical College News—Mr. Alba B. Johnson, president of the board of trustees of Jefferson Medical College and Hospital, died January 8 of heart disease aged 77. Mr. Johnson was a former president of the Baldwin Locomotive Works and was active in civic, social and cultural organizations. William K. Gregory, Ph.D., professor of vertebrate paleontology, Columbia University, delivered the annual Alpha Omega Alpha Lecture at Jefferson, January 18, on "The Origin, Rise and Decline of Homo Sapiens."

Annual Meeting on Economics—The Philadelphia County Medical Society held its annual meeting on medical economics, January 23. Speakers were Drs. Francis F. Borzell, chairman of the committee on medical economics of the Medical Society of the State of Pennsylvania, whose subject was "Organized Medicine and Social Insurance", Nathan B. Van Etten, New York, vice speaker of the House of Delegates of the American Medical Association, "The Medical Economics Program for 1935," and Arthur C. Christie, Washington, D. C., "Some Problems of Medical Care: Is Health Insurance the Solution?"

TENNESSEE

Bills Introduced—S. 83 proposes to create a council of public health, which "shall approve all the rules and regulations formulated by the department of public health" said council to consist of three licensed physicians, one licensed dentist, one sanitary engineer, one member of the Tennessee Congress of Parents and Teachers, one member of the Tennessee Federation of Women's Clubs, one educator, and one member of the American Legion Auxiliary, Department of Tennessee. S. 85 proposes to repeal the laws regulating the registration of nurses and to enact a new nursing practice act. Applicants for licenses must be high school graduates and be graduates of accredited schools of nursing, giving courses of not less than two years. A person not registered may practice nursing but not as a registered, trained certified or graduate nurse and may not use the title, letters or anything else to indicate that he or she is a registered nurse. H. 130 proposes to authorize the sexual sterilization of certain socially inadequate inmates of the Hospital for the Criminal Insane, of the Central State Hospital, of the Eastern State Hospital, of the Western State Hospital, of the Tennessee Home for Feeble-minded Persons, and of the state penitentiary.

TEXAS

Bill Introduced—H. 10 proposes to limit the hours of employees engaged in selling, at retail, drugs and medicines, and compounding physicians' prescriptions, to not more than an average of nine hours a day or 108 hours in any two consecutive weeks.

Medical Assembly in San Antonio—The third International Post-Graduate Medical Assembly of Southwest Texas will be presented in San Antonio, January 29-31. Among guest speakers will be

- Dr. Walter C. Alvarez, Rochester, Minn., "Diagnosis of Gastro-Intestinal Disease from a Good History"
- Dr. Joseph Brennemann, Chicago, "Present Status of Specific Prophylaxis and Serum Therapy in the Infectious Diseases of Childhood"
- Dr. Edward W. Alton, Ochsner, New Orleans, "Treatment of Varicose Veins"
- Dr. Clifton M. Miller, Richmond, Va., "Errors of Refraction and the Importance of Correcting Them"

Several physicians from Mexico will also appear on the program. There will be general sessions each day and evening, with sectional meetings at noon luncheons.

Society News—Drs. Robert K. Lowry, Seymour, and William P. Farrington, Mundy, addressed the Baylor-Knox-Haskell Counties Medical Society, Knox City, Nov. 13, 1934, on "Incent's angina and typhoid fever, respectively." Drs. Charles W. Flynn and Ozro T. Woods, Dallas, addressed the

Henderson County Medical Society, Trinidad, Nov. 5, 1934, on diseases of the gallbladder and tumor of the breast, respectively. Speakers at a meeting of the Tom Green-Eight Counties Medical Society in San Angelo, Nov. 5, 1934, were three San Angelo physicians: Drs. Floyd T. McIntire, on "Etiology and Treatment of Arthritis", Rufus L. Powers, "Episiotomy and Low Forceps in Primipara" and William E. Schulkey, "Infections of the Hand." Drs. James Howard Shane and Charles H. Warren addressed the Dallas County Medical Society, January 24, on "Important Factors in the Management of Urinary Infections" and "Nonspecific Granulomas of the Gastro-Intestinal Tract," respectively.

VIRGINIA

Society News—Drs. Ernest Scott Elliott, Independence, Walter A. Porter, Hillsville, and Joseph Coates presented papers on pneumonia at a meeting of the Carroll-Grayson Counties Medical Society at Galax, Dec. 10, 1934. Drs. Marcellus A. Johnson Jr. and Julius D. Willis addressed the Roanoke Academy of Medicine, Dec. 3, 1934, on "A New Method for Treating Fractures of the Leg" and "Pericardial Accumulations," respectively. Drs. Meade C. Edmunds, Petersburg, and William G. Crutchfield, Richmond, among others addressed the Southside Virginia Medical Association, Dec. 11, 1934, on "Pulmonary Abscess Following Tonsillectomy" and "Acute Head Injuries," respectively. Drs. Griffin W. Holland, Eastville, and William W. Kerns, Bloxom, presented papers on dislocations of the shoulder joint and pneumonia, respectively, at a meeting of the Eastern Shore of Virginia Physicians' Journal Club, Dec. 11, 1934, at Nassawadox.

WEST VIRGINIA

Society News—The Marshall County Medical Society at its meeting, Dec. 11, 1934, adopted a resolution protesting against "misleading advertising of nostrums" over the radio and through other channels.

Health Officers' Meeting—The West Virginia Public Health Association and the State Health Officers' Conference met in joint session at Charleston, recently. Among speakers listed on the program were

- Dr. William H. Park, New York, "New Ways for Old in Diphtheria"
- Dr. Eugene L. Bishop, Nashville, Tenn., "Public Health—What It Is and How It Is Administered"
- Dr. Oliver C. Wenger, of the U. S. Public Health Service, Hot Springs National Park, Ark., "Modern Control and Treatment of Syphilis from a Public Health Standpoint"
- Dr. Harry E. Kleinschmidt, New York, "What We Can Do to Control Tuberculosis"
- Dr. Eric M. Matsner, New York, "Some Neglected Phases of Maternal Health"

Dr. Turner E. Cato, New Cumberland, was elected president and Dr. John Thames, Charleston, secretary.

Conference of County Secretaries—The annual conference of the secretaries of county medical societies was held at the headquarters of the West Virginia State Medical Association, Charleston, January 3, with Dr. Joseph A. Striebich, Moundsville, as chairman. A discussion of emergency medical service under the FERA was led by Dr. Grattan G. Irwin, Charleston, and one on nursing service by Dr. Robert C. Hood, Clarksburg. Dr. James R. Bloss, editor of the *West Virginia Medical Journal*, spoke on "The County Secretary and the State Journal". Dr. Eugene S. Brown, Summersville, on "Functions of the Average County Medical Society," and Mr. Joe W. Savage, executive secretary of the state association, on pending legislation. Dr. Rome H. Walker, Charleston, president of the state association, welcomed the secretaries.

GENERAL

Infantile Paralysis Research Fund—Hundreds of entertainments will be held throughout the United States on President Roosevelt's fifty-third birthday, January 30, for the benefit of the President's Birthday Ball Commission for Infantile Paralysis Research. The President will address the guests in a nationwide broadcast late in the evening. This year 70 per cent of the funds will be distributed among local communities to further their infantile paralysis work and 30 per cent to the national fund for research. The fund will be augmented by contributions of 25 cents from each person who signs a multiple signature birthday greeting to the President, and the signatures will be bound in book form in New York.

Requests and Donations in 1934—Gifts for philanthropic purposes increased during 1934, according to a survey made by a firm of fund raising consultants in six large cities, but bequests declined. Health ranked fourth in the eight classifications for which the study was made. In 1934 gifts for promotion of

health amounted to \$3,875,406, in comparison with \$1,178,600 in 1933. Bequests, however, declined from \$16,349,835 in 1933 to \$7,904,709 in 1934. The total amounts contributed for charitable objects in New York, Chicago, Philadelphia, Baltimore, Washington and Boston for the two years were \$142,533,548 for 1933 and \$112,602,266 in 1934. The decline in bequests in the six cities was from \$99,840,290 to \$58,579,670. Organized relief received the largest support, \$27,544,857, about \$5,000,000 less than in 1934. Increased support for education was evident in 1934, gifts having increased to \$13,325,301 from \$4,056,828 in 1933.

Changes in Status of Licensure—The State Board of Medical Examiners of Florida reports the following action taken at its meeting in Tampa, Nov. 12, 1934:

Dr. Joseph M. De Gaetani, whose last known address was Miami, license revoked on two charges, that his license and diploma were fraudulently obtained through the old eclectic board and that he recently committed a criminal abortion. He was tried in the criminal court of Dade County on the latter charge but was pronounced not guilty.

Dr. Harper L. Proctor, Jacksonville, license revoked, now serving a prison sentence for having violated the Harrison Narcotic Act.

Dr. Edward K. Tullidge, license revoked June 1931 on the ground that he had falsified in making application to the board, having asserted that he had never been convicted of a crime involving moral turpitude. It was later discovered that he had served a term in a federal prison. The supreme court reversed the action of the board on the ground that Tullidge was improperly notified when his trial took place. The license was revoked again at this meeting on the same charge.

The Board of Medical Examiners of the State of Oklahoma reports the following:

Dr. John Milton Thompson, Walters, license suspension changed from five years suspension to one year's suspension and four years probation. He may thus begin practice March 13, 1935.

Physicians Requested to Help Find Dr. Bigelow—Massachusetts authorities ask physicians throughout the country to watch for Dr. George H. Bigelow, director of the Massachusetts General Hospital and former state health commissioner, who has been missing since Dec. 3, 1934 and may be suffering from amnesia. Dr. Bigelow is 6 feet tall, weighs about 175 pounds, and has deep blue eyes and a heavy shock of black hair, closely cut and slightly gray at the temples. He is of rangy build. When he left home, he wore a soft brown felt hat, a black overcoat with a velvet collar, a brown suit, tan rubber-soled shoes, and a white shirt. He wore a square silver wrist watch with a leather strap and carried a brown pigskin brief case. He is 44 years of age. He disappeared, December 3, having left his home in Milton for his office in the Moseley Building at the Massachusetts General Hospital, Boston. He was to appear at 8 o'clock Tuesday evening, December 4, at the Staten Island Hospital to speak, and on Wednesday at the American Society for the Control of Cancer in New York City. The Massachusetts Department of Public Safety has the fingerprints of Dr. Bigelow. Hospitals are requested to take the fingerprint of all unidentified amnesia victims and forward the prints to the commissioner of public safety, Col. Paul G. Kirk, State House, Boston.

Dr. George H. Bigelow

Medical Bills in Congress—*Change in Status*. H. R. 3410, the Independent Offices Appropriation Bill, has passed the House and Senate. A Senate amendment which is subject to acceptance or rejection by the House authorizes payments not to exceed \$500,000, to state institutions caring for and maintaining veterans suffering from neuropsychiatric ailments, who are in such institutions on the date of the enactment of the act. *Bills Introduced*. S. 1130, introduced by Senator Wagner, New York; H. R. 4120, introduced by Representative Doughton, North Carolina, and H. R. 4142, introduced by Representative Lewis, Maryland, propose to alleviate the hazards of old age, unemployment, illness and dependence, to establish a social insurance board in the Department of Labor, to raise revenue, and other matters. These bills propose to create a social insurance board in the Department of Labor, which is to be authorized among other things to study and make recommendations as to legislation providing for health insurance. They provide federal subsidies contingent on state plans being acceptable to the chief of the Children's Bureau to promote maternal and infant welfare to care for crippled children and to provide for child welfare services. Federal

subsidies are further provided for the development of state and local health work. S. Res. 55, introduced by Senator Sheppard, Texas, proposes to create a Senate Committee on World War Veterans' Legislation. S. 1132, introduced by Senator Moore, New Jersey, proposes to authorize the Secretary of the Treasury to insure loans made by banks and other financial institutions, for the purpose of financing payment for medical and dental services. H. R. 19, introduced by Representative Fulmer, South Carolina, proposes to prohibit the sending of unsolicited merchandise through the mails. H. R. 99, introduced by Representative Smith, Washington, and H. R. 2071, introduced by Representative Taylor, Tennessee, propose to reenact all laws granting compensation, medical, hospital or domiciliary treatment to veterans that were repealed by the act of March 20, 1933. H. R. 100, introduced by Representative Smith, Washington, proposes to reenact laws relating to pensions for Spanish-American War veterans that were repealed by the act of March 20, 1933. H. R. 150, introduced by Representative Cochran, Missouri, proposes to authorize the Reconstruction Finance Corporation to make loans to any public or private hospital organized under the laws of any state. H. R. 156, introduced by Delegate Dimond, Alaska, proposes to extend the facilities of the Public Health Service to seamen on government vessels not in the military or naval establishments. H. R. 1404, introduced by Representative Lundeen, Minnesota, proposes to grant pensions and increases of pensions to certain soldiers and sailors of the war with Spain, the Philippine insurrection and the China relief expedition, and their widows and dependents. No pension is proposed by the bill for contract surgeons of the Spanish-American War. H. R. 2760, introduced by Representative Dingell, Michigan, proposes to authorize the Reconstruction Finance Corporation to make loans to nonprofit benevolent charitable corporations operating homes, hospitals or orphanages for sick and infirm persons, indigent persons of old age, mental defectives or orphans. H. R. 2802, introduced by Representative Johnson, Oklahoma, proposes to protect labor by providing for old age and disability pensions. H. R. 2813, introduced by Representative Kvale, Minnesota, proposes to extend the privileges of compensation and hospitalization to certain American citizens who volunteered in the French military forces without surrendering their American citizenship. H. R. 2828, introduced by Representative Lundeen, Minnesota, proposes among other things, to reenact all laws granting medical or hospital treatment, domiciliary care, compensation and other allowances to veterans and the dependents of veterans of the Spanish-American War, including the Boxer rebellion and the Philippine insurrection, which were repealed by the act of March 20, 1933. H. R. 3005, introduced by Representative Hoepfel, California, proposes to establish federal research fellowships to college graduates for the purpose of conducting research work for the benefit of the various departments of the federal government or for private industry in medicine, surgery, bacteriology, hygiene and other fields. H. R. 3423, introduced by Representative Tinkham, Massachusetts, proposes to direct the retirement of acting assistant surgeons of the United States Navy at the age of 64 years. H. R. 3635, introduced by Representative Mitchell, Tennessee, proposes to erect a veterans' hospital in middle Tennessee. H. R. 3972, introduced by Representative Mead, New York, proposes to prevent the manufacture, shipment and sale of adulterated or misbranded foods, drugs and cosmetics and to prevent the false advertisement thereof.

FOREIGN

Dysentery in Japan—The *New York Times*, January 11, reported an epidemic of infantile dysentery in Kawasaki, an industrial suburb between Tokyo and Yokohama. It was said that 850 cases had been reported since January 3, with 101 deaths.

Medical Center in Shanghai—Construction has been started on a medical center in Shanghai, China, according to the *New York Times*. Buildings will be erected on a twenty-one acre tract donated by the Rockefeller Foundation to the board of directors of the Shanghai Medical Center. The head of this board, which is made up of twenty-seven Chinese government officials, business men and physicians, is Dr. H. H. Kung, minister of finance of China. The first structure will be a hospital with accommodations for about 550 patients, but the plans call for an ultimate capacity of 1,000. The hospital will be financed with funds solicited by the Shanghai Medical Center, \$200,000 has already been subscribed. The Chinese government will finance the construction of a building on the same site for the National Medical College, plans for which have already been approved. This project will cost about \$125,000.

The British Medical Association and the Attempt of the Osteopaths to Obtain Registration

The second reading in the house of lords of the bill for the registration and regulation of osteopaths was reported in a previous letter. A special committee of the council of the British Medical Association is preparing a memorandum on osteopathy, and the medical secretary has prepared the following preliminary criticism. If the bill becomes law, two different classes of practitioners recognized under different acts will be set up. The purpose of the medical acts now in existence was to draw a clear line between persons who have and persons who have not passed through the authorized medical curriculum. This will be defeated. The student of osteopathy, after a course of instruction of considerably less duration than the medical student will be admitted to the register of osteopaths and entitled to hold himself out to practice in the wide field of medicine. A new type of practitioner will appear and the public will have to distinguish for itself between those who have satisfied the full requirements of the General Medical Council, those who have satisfied the lesser and different requirements of the Board of Registration of Osteopaths and those who have received no recognized training at all. Today any physician is free to practice any form of treatment which he regards as beneficial. Neither belief in osteopathy nor the practicing of it can exclude any one from the Medical Register. The General Medical Council, which controls practice, is expressly prohibited from making any distinction between practitioners following different theories or methods of treatment. Those who have a knowledge of the human body in health and disease sufficient to justify them in engaging in medical practice can satisfy the requirements of the General Medical Council and then adopt what methods they like.

Of the "osteopathy" which the bill is to recognize, little information is given by those claiming registration. It is described as a system of treatment by manipulation methods. Yet in clause 8 of the bill it is laid down that no one unless registered under this act shall practice osteopathy. The course of instruction is shorter than that demanded of the medical student. The effect of this would be to attract a new and inferior type of student. Yet on admission to the register he will hold himself out as qualified to practice practically the whole field of medicine. Such a register will prove a back door to medicine. Is this in the public interest? As the law stands the public can seek its treatment where it likes with the Medical Registrar to enable it to distinguish those who have satisfied minimum standards. Soon there will be demands from other cults and registers will multiply. The bill precludes any one not registered as an osteopath from practicing osteopathy, which is described merely as a system of manipulative treatment. It follows that physicians are to be prevented from using manipulative treatment. No monopoly of any particular system of treatment should be created. According to the bill the proposed board of registration will consist of a chairman appointed by the privy council, two persons representative of science, not being physicians appointed by the ministry of health and eight osteopaths five of whom are to be appointed by the British Osteopathic Association. How can a board thus created have an intimate acquaintance with medical science. Medical education must rest on a broad scientific foundation so that the student may be both competent in practice and trained to judge the value, or want of value of future developments. Such a training cannot be provided in institutions restricted to a particular theory.

Speaking at the annual dinner of the Medico-Legal Society Lord Horder made some crucial objections to the proposed registration. It was difficult for him to conceive how it was possible to erect a single therapeutic measure into a system of medicine, to eliminate the art of diagnosis and the basis of all medicine which was pathology, and proceed straight to treatment. He wondered what was going to happen to the British public if for diagnosis and the pathology that underlay diagnosis there was substituted one single treatment, however important, and if the man who had this one method of treatment at his command was to be elevated to the position of a registered medical practitioner. Still, if the public wanted it, let it be tried out. He did not think that physicians should protest too much against that sort of thing. The more they protested the more would osteopaths consider themselves martyrs and martyrdom was valuable propaganda.

The Edinburgh Chair of Clinical Medicine

The important Edinburgh chair of clinical medicine has been rendered vacant by the retirement of Prof Edwin Bramwell, who is widely known by his writings on myasthenia gravis, epilepsy and spinal tumors. He is the oldest son of the late Sir Byrom Bramwell, a great clinician who specialized in neurology at the end of the last century. Professor Bramwell is succeeded by Dr Edwin Matthew, physician to the Royal Infirmary.

Statistics on the Public Health for 1933

The Registrar-General's Statistical Review for 1933, which has just been published, shows that the infant mortality was 64 per thousand live births. The rates for 1930, 1931 and 1932 were respectively 60, 66 and 65. Thus the rate for 1933 was only slightly in excess of that for 1930, which was the lowest on record. The death rate from tuberculosis was the lowest on record, being 824 per million of population, while the "comparative mortality" from cancer showed a slight decline. The death rate from puerperal sepsis was 175 per thousand births, which was 0.20 more than in 1932 but 0.09 less than in 1930. The death rate from suicide was 140 per million living, a decrease of 3 on the rate for 1932, which was the highest on record. These figures again show that no deterioration of the condition of the people has taken place, in spite of the unprecedented and persistent unemployment. Indeed, the general death rate from all causes, 123 per thousand, was only 0.9 above that for 1930, the lowest on record which is attributed to the exceptionally mild weather of the first quarter of that year. It may be added that the 1933 birth rate, 144 per thousand population, was the lowest ever recorded.

Treatment of Asthma by Exercises

The Asthma Research Council, whose last report was reviewed in THE JOURNAL, December 29, has issued an illustrated booklet on the treatment of asthma by exercises. The object of treatment is to restore the lungs and chest to normal size or to prevent distention from occurring. Ordinary breathing exercises, the object of which is to increase the expansion of the chest, are useless, as the asthmatic patient is already capable of expanding his chest to the maximum. If an asthmatic patient is told to breathe deeply, his respiration is seen to be almost entirely upper thoracic, in chronic cases the lower part of the chest is already fully expanded and remains immobile, the diaphragm being used only to a slight extent. The exercises are designed to teach the patient first, to use the lower part of the chest as well as the upper and secondly, to use the diaphragm more. They can be performed reclining on a bed, sitting on a stool or standing according to the patient's state of health. In any case the body should be held loosely with the arms by the sides. The patient should face a mirror, so that he can watch the effect of the exercises on his chest. They should be carried out with the aid of a remedial gymnast, but

the patient should practice some of them daily for the rest of his life, even if he remains free from asthma for months or years. They should be performed before breakfast, when the patient is feeling fresh, before going to bed to clear the lungs before sleep, and on the first sign of an impending attack, which may be aborted. Properly performed, they should cause wheezing and often coughing at the end of expiration. The exercises are mainly expiratory and the patient assists expiration by pressure with his hands on the lower part of the chest.

The Ear and Industrial Medicine

The ear and industrial medicine was the subject of a discussion at the French otorhinolaryngologic congress in October 1934. The first paper was by Causse. Only five countries (Bulgaria, Czechoslovakia, Germany, Mexico and Russia) have placed deafness that is the result of the worker's occupation on an equal footing, so far as indemnity is concerned with invalidity due to lead or mercury poisoning. There is no law of this kind in France.

Deafness from the standpoint of industrial medicine may be the result of injury to the skull, electricity, compressed air or intoxications and is also found in those engaged in occupations such as metallurgy and steel construction. The majority of cases of deafness in workers are due to traumatism of the head. Longitudinal fractures of the petrous portion of the sphenoid traverse the middle ear, while transverse fractures are more likely to involve the internal ear. The otologist is consulted most frequently in cases in which there has been a simple concussion of the brain without accompanying skull fracture. There is an absence of any relation between the degree of the injury and its sequelae. The patients in this first group are more likely to suffer from deafness than from vertigo.

Deafness due to electricity does not occur very often. Deafness may result in cases in which the current has not traversed the ear. In patients in this group the signs of deafness may appear quite a long time after the accident, thus making it difficult to determine the part the electrical shock has played. Accidents due to lightning belong in the same group. In divers or caisson workers the deafness is due to microscopic air emboli as shown by Paul Bert, the cochleovestibular apparatus being especially affected. One finds a sudden deafness or vertigo or both in most cases, but in some the symptoms do not appear immediately. Deafness or vertigo in such cases is not always permanent. Deafness due to intoxications is also not frequent, being seen most in the lead and next often in the mercury, arsenic or phosphorus industries. Deafness in those occupied in boiler or other riveting or railroad work is of increasing interest to otologists and is growing in proportion to the development of machinery in general. The otologist in making his report must always keep in mind the possibility of malingering, hence a thorough knowledge of the physiology of the internal ear is necessary.

In the discussion, Barraud of Lausanne emphasized the part played by modern mechanical devices and called attention to the deafness of soldiers in machine gun companies. Jacques of Nancy said that all cases of head or face injury should be examined as soon as possible after the accident.

Relation of Diabetes to Tuberculosis

A study of ninety-five cases observed at Labbe's clinic has been made by Thierry. Pulmonary tuberculosis is the cause of death in 40 per cent of diabetic patients and this percentage rises to 60 in severe diabetes accompanied by lack of assimilation of proteins. In severe cases of diabetes without such a metabolism disturbance tuberculosis is fatal in 30 per cent.

Tuberculosis may complicate diabetes at any period of life even in children in whom insulin has reduced the likelihood of a coma.

Certain types of infection, especially those due to pneumococci, favor the rapid development of pulmonary tuberculosis in diabetic patients. The latter disease in general favors such a complication on account of its tendency to disturbance to protein metabolism and the hyperglycemia. Reciprocally, an incipient tuberculosis or at least one subject to frequent acute exacerbations increases the severity of the diabetes. It causes acidosis to appear in 90 per cent of diabetic patients, and in 40 per cent such an acidosis is not compensated for, with resultant decrease in the alkali reserve and the development of a precomatous state. Tuberculosis causes carbohydrate intolerance and hence recurrence of the severe diabetic symptoms at the same time as the tuberculosis begins to manifest more acute signs. In 15 per cent of patients with diabetes, the tuberculosis appears in a pneumonia like manner. In about 16 per cent the onset is insidious with emaciation, loss of appetite and a subfebrile condition, while in 71 per cent there is a marked rise of temperature. Pneumothorax treatment should always be accompanied by reduction of carbohydrates and the administration of insulin. Such a treatment has resulted in a mortality of only 65 per cent during a period of four years in Labbe's service. Untreated pulmonary tuberculosis complicating diabetes results fatally almost invariably in eighteen months at the most.

Gonorrhea in Its Relation to Pregnancy

A careful study of 142 cases made at one of the large Russian maternities by Astrinsky and Grinner appears in the November 1934 issue of the French journal *Gynecologie et obstetrique*. The gonorrhea was verified bacteriologically in 135 of the 142 cases, and in the remainder the clinical changes were the basis of the diagnosis. Gonorrheal cervicitis and salpingitis do not exclude the possibility of conception. Pregnancy can activate a latent gonorrhea. The disease presents itself in a much more acute manner during pregnancy than in the nonpregnant female. Such complications as postpartum hemorrhage, abortion during pregnancy and hemorrhage during the puerperium are common. The presence of gonococci in the lochia does not give rise to any postpartum febrile reaction. The later the gonorrheal infection takes place in pregnancy, the more severe are the postpartum complications. One ought to treat gonorrhea during pregnancy in the same manner as in the nonpregnant patient.

Honorary Degree Bestowed on Professor Eiselsberg

At the beginning of each academic year it is the custom for the University of Paris to give honorary degrees to those whom the various faculties, law, sciences, letters and medicine recommend. Last year Dr. Harvey Cushing was thus honored, and this year Professor Eiselsberg of Vienna. Dean Roussy of the Faculty of Medicine eulogized Professor Eiselsberg in an eloquent address as being one of the pioneers, along with Billroth, of modern surgery. The career of Professor Eiselsberg has been a long one, and he has shown the unbiased method of thinking and the desire to investigate every new problem, which represents the highest type of modern research. Eiselsberg's work on the surgery of the thyroid, of the alimentary canal, of tumors of the nervous system and especially on that of the hypophysis, has been the means of aiding the rapid development of these subjects. Even though he has retired from teaching at the University of Vienna, Eiselsberg not only continues to work in his large private practice but follows with the keenest interest the progress of that branch of medicine to which he contributed so much. Many American surgeons who have visited the clinic of Professor Eiselsberg at Vienna will hail this recognition of his work as a justly merited honor.

Death of Dr Lucien Camus

The director of the vaccine laboratory of the Academy of Medicine, Dr Lucien Camus, died early in November 1934. He rendered invaluable services in the development of the technique of preparation of variola vaccines and the organization of centers all over France for such preparation. His work on the effect of currents of short wavelength on variola vaccine is well known. His annual report to the Academy on vaccination as a prophylactic measure against variola, was one of the most thorough of its kind.

The Cost of Health Insurance in 1933

The expenditures of the municipal *krankenkassen* during the year 1933 have just been made public. The status of the *krankenkassen* as such has already been reported. The total expenditures (inclusive of losses incurred by the disposal of property and by other disbursements) of the municipal *krankenkassen* reached during 1933 the total of only 6766 million RM compared to 7132 million RM in the preceding year. In apportioning the total expenditures for 1933 to each member the sum is 59.84 RM, compared to 60.80 RM in 1932. The greatest portion of the total expenditures (79.6 per cent) was disbursed for sick benefit to the insured and their families. The average expenditure for sick benefit for each member and his family was 47.63 RM. Of this amount the disbursement for medical and dental services was 18.72 RM, for medicines 6.80 RM, for hospitalization and other nursing care 10.50 RM, and for sick pay, household and other expenditures, 11.60 RM.

The expenditures for the care of puerperal women amounted to 43.2 million RM in all that is to 64 per cent of the total disbursements. During 1932, 51.4 million RM was expended for this purpose. The disbursements for burial expenses amounted to 4.7 million RM during 1933. The costs of administration were 82.8 million RM in 1933 compared to 89.5 million RM in 1932 for each member these expenses have been decreased from 7.62 to 7.32 RM. The administration expenditures amounted to 12.2 per cent of the total disbursements and to 12.8 per cent of the income from premiums.

Within the scope of the benefits to the insured and the members of their families the treatment by licensed physicians (inclusive of services in kind and of transportation costs) called for 25.3 per cent of the income from premiums during the year 1933. 7.1 per cent of the income from premiums was expended for dental care, 10.5 per cent for medicine, 17 per cent for care in hospitals (exclusive of sojourns in spas) and 19.3 per cent for sick pay in cash.

New Details of Professional Affairs

The newly founded Academy for Medical Graduate Work in Berlin, which succeeded the older graduate institute, instructed about 1,200 physicians during the summer semester of 1934 in fifty courses. The majority came from the various parts of Germany (non-Aryan citizens of the Reich are not admitted to these courses). This academy has a staff of about 300 docents, who have at their disposal about 30,000 beds in the various hospitals of Berlin. The academy is supported by the city of Berlin.

The regulations so far have not made it possible to exclude physicians with a questionable mental status. Now it has been decreed that admittance to the medical examination and to the practical year following the state medical examination is to be refused, when as the result of a mental disease or of some addiction, the candidate has not the reliability that is required for medical practice. To prevent the admittance of such persons into the profession the directors of hospitals are requested

to indicate their observations to this effect in the certificates of the interns or to report to the ministry.

The federal commissioner decreed that all medical societies of Berlin inform him of the time and the program of their next session early enough so that it may be approved. The scientific societies, the National Socialistic Physician's Association and the Association of German Physicians are exempted from these regulations.

The Berlin director of the organization of the insurance physicians of Germany decreed that insurance physicians who desire to spend their vacation in a foreign country must report this in advance to the organization and state the duration, the reason of their foreign sojourn and their address in the foreign country. The furlough in a foreign country requires in all cases previous official consent, a prolongation is generally not permissible.

The chairman of the physician's organization in Düsseldorf sent a circular letter to the members of his organization, which reads as follows: The Marienhospital in Düsseldorf, at the election, August 19, rejected the leader and National Socialism by more than 50 per cent. This election result signifies a challenge to the profession, to the city and beyond that to the state. The medical profession of Düsseldorf will attempt to redress this alien attitude by a strict boycott of the hospital up to a complete economic destruction. I therefore decree that transfer of patients to the Marienhospital is forbidden. The German physicians who send their patients to this hospital in spite of this regulation will be named publicly in a circular letter. This letter was published in a great medical publication.

Recommendations Concerning Abortifacients

The measures adopted by Germany in the campaign against abortion constitute one of the causes of the increase in the birth rate. However the professors of legal medicine have reached the conclusion that the new penal regulations in regard to the sale of abortifacient instruments have not accomplished their aim in the desired extent. For this reason they advocate the following extension of the regulations. All instruments and apparatus that may be used by the public for abortive measures, for instance, so-called uterine catheters, uterine cannulas or tubes, uterine speculums, irrigation apparatus and especially so-called balloon syringes with long thin tubes, as well as the various types of pessaries, are to be withdrawn from the open market. All these should be sold only as medical instruments in the stores specializing in them and by the apothecaries. They should be sold only with a physician's prescription. If necessary, the manufacture of such instruments that are intended for abortifacient purposes should be prohibited.

The Bureau for the Welfare of Youth

Dr Lottig of Hamburg has explained that the physician's work in the bureau for the welfare of youth is the most interesting of the social activities of the physician. The medical points of view are of especial importance in connection with the work of the youth welfare bureau. The hereditary problem is the focal point in every case. The number of charges of the Hamburg youth bureau averages 35,000 yearly and among them are 4,600 inmates of institutions, of whom 1,600 have been put into institutions because of inadequate training and destitution. The various forms of productive welfare work are extended yearly to about 10,600 charges. The part played by physicians in this work is indicated by the fact that more than 3,400 cases require psychiatric consultation. It is the task of the neurologic-psychiatric-pedagogic section to make a prompt but thorough diagnosis. Other important spheres of action are the clinical diagnosis in the observation ward, cooperation in the guardianship decisions in the juvenile court, in the estimation of juvenile witnesses in penal lawsuits in arrangements for adoptions and finally in the study of the numerous cases of sterilization.

Dangers to Health of Uninterrupted Working Periods

The medical committee of the German Society for Industrial Hygiene has set up 'principles for regulating the hours of work and of recesses from the standpoint of health.' These principles state that the uninterrupted working period is detrimental to health, and they reject it. They recommend the introduction of a divided working time wherever the management of the establishment and the transportation permit it. They recommend a noon recess of two hours, so that the worker may be enabled to go to his home. When this is impossible, there should be suitable recesses so that the workers may take a warm meal at their place of work at noon.

Death of Professors His, Strasburger and Hahn

The well known internist of the University of Berlin, Prof Wilhelm His, died Nov. 10, 1934, shortly after his retirement on account of a chronic ailment. His accomplishments were recounted here a short time ago, on the occasion of his seventieth birthday (*THE JOURNAL*, Feb 10, 1934, p 471).

The well known internist and the director of the medical polyclinic of the University of Frankfurt-on-Main Prof Dr Julius Strasburger, died, Oct 27, 1934, at the age of 63. Shortly before, he had resigned from his teaching position as ordinarius. In addition to the polyclinic he directed the institute for physical therapy. Together with Adolf Schmidt he had published important studies on intestinal disorders.

Prof Dr Martin Hahn, who for many years was ordinarius for hygiene at the University of Berlin, died at the age of 70. After his research work in the cholera district of Astrakhan, as a young man, his scientific career was assured. As the assistant of Hans Buchner in Munich, who received the Nobel prize, he became known through his collaboration in research on zymase. He was one of the first to devote himself to the problem of physical work and occupational therapy. He greatly promoted social and industrial hygiene and sanitation and early gave all the force of his authority to the racial hygiene movement.

Nov 30, 1934

Essay on Recovery of Medical Prosperity

The *Japanese Medical Journal* offered a prize for an essay on "How to Tide Over the Present Difficult Situation in the Medical Profession." In a six months period eighty-three essays were received, most of them written by practitioners. The winners were recently made known. Dr K. Nakadate won the first prize, 500 yen. In his essay he said that the causes of the present difficulties are, first, the surplus of physicians, which must be corrected by changing the system of medical education so as to divide the specialists and the general practitioners. The last two years in the medical college should be devoted to specialized education and the previous years to general education. A certificate for practice should be given after two years' practical training in approved hospitals after the student has finished the college courses. In the second place, any treatment done by those who are not physicians but are now sanctioned by the local governments should be entirely prohibited except when the practitioner recommends that they treat a patient under his personal guidance. Third, any health benefit associations organized under the pretext of lower medical fees should be dissolved, as they tend to commercialize the profession and prevent patients from exercising a free choice of physician. Fourth, the indiscriminate manufacturing of new medicines should be ended by careful regulation. The doctor with little experience is more apt to administer expensive new medicines and this is one reason for the high cost of medical care. The selling of medicine by practitioners has caused many complaints, and the lower classes are inclined to refrain from consulting the doctor lest they be obliged to

pay too much. This is an essential cause of the present trouble, to say nothing of the general business depression. Fifth, medical advertisements, especially on the roadsides or in the stations or on roofs, should be utterly prohibited. They destroy dignity and induce the people to despise medicine. Supplementary education to promote the practitioner's knowledge should be published by the medical association in a periodical with the latest scientific research and clinical experiences of physicians. Concluding, he says that there should soon be established the most rational medical system. The tendency of regarding medical practice as a commercial product he despises. He holds that medicine is a benevolent art and should be practiced in this principle.

Death of Dr Kagami Fujinami

Dr Kagami Fujinami, honorary professor of the Kyoto Imperial University, died November 18, aged 64. He obtained fame through his studies of a disease due to a Japanese blood sucking parasite for which he was awarded the Imperial prize in the Imperial Academy in 1918. Thanks to his research, this disease was completely stamped out of those provinces where it formerly raged. A monument stands there to commemorate his achievement. He was a man of noble character from his boyhood, and he was always above riches and honors. He was called an infant prodigy and once was awarded a prize while still in primary school for reading a short story, when Emperor Meiji happened to visit his school. He graduated from the Tokyo Imperial University in 1895 and went to Germany, where he stayed four years. On returning home he was appointed professor at Kyoto. Dr Goichi Fujinami is his younger brother.

The Age Limit for Professors

The present age limit for professors of the imperial universities was first established in 1918 in the Tokyo Imperial University on the motion of professors of the medical department. Since then the question has been raised whether it is proper or unreasonable, but it has been faithfully obeyed as an unwritten law though it was merely a gentlemen's agreement. Sixty years, some think, is too early to retire. Prof Dr K. Manabe, who has been about a year in Europe and America, has written on this subject in the *Varsity Press*, saying that the age limit should be abolished, as the age limit in Italy is 75, in Greece and France 70, in Germany from 65 to 68, and in Switzerland 70 years. Some are of the opinion that the age of 60 is the time when man is intellectually in his prime. It is absurd to apply the age limit uniformly without considering some personal factors. This law is now enforced only in the government universities, with one exception. If there is any good reason for this law, it ought to be enforced among other colleges. Some who have retired under this system have soon after been appointed to important offices. That there are many positions open to the retired professors better than the old post shows that it is not a disgrace to retire at 60, on the other hand, the present plan permits energetic young scholars to find their way to a professorship.

Personals

Dr Sennosuke Yokote, director of the Natural Science Research Institute at Shanghai, China, has tendered his resignation on account of illness. His successor is said to be Dr Shinzo Shimjyo, ex-president of Kyoto Imperial University.

Prof Inokichi Kubo of the Kyushu Imperial University medical department will resign shortly, as he has reached the age limit. He was the founder of the section of otorhinolaryngology and has been professor for thirty-five years. He and his wife have attained fame as poets.

Dr Masanori Nakazumi will be promoted to professor and hold the new chair of roentgenology in the Imperial University of Tokyo.

Marriages

JOHN ROLAND UPTON, San Francisco, to Miss Anna Logan Sloan of Paris, France, in New York, Dec 25, 1934

JOHN J SHOBER, Philadelphia, to Miss Emelya M McCormick of Atlantic City, N J, Dec 22, 1934

PAUL Q DANIEL, Deltaville, Va, to Miss Salome Virginia Butler of Richmond, Nov 1, 1934

ELLIS R CRANDLE, Gorham, Ill, to Miss Virginia Lee Williams of St. Louis, Nov 28, 1934

CAESAR F SARNI, Norristown, Pa, to Miss Antoinette Lalonde of Bangor, Oct 27, 1934

EDGAR CHILDREY JR., Rochester, Minn., to Miss Irene Hill of Piqua, Ohio, Oct 20, 1934

ROBERT H McKELVEY, Bethesda, Ohio to Miss Martha Talbott of Ellsworth, recently

WALTER L WINKENWERDER to Miss Eleanor Zouch both of Baltimore, Dec 1, 1934

SAMUEL J WEITZEN to Miss Elsie Glasser, both of New York, January 15

Deaths

James Francis Coupal, Washington, D C., Tufts College Medical School, Boston, 1909 member of the Massachusetts Medical Society, the Medical Society of the District of Columbia, and the American Association of Pathologists and Bacteriologists served during the World War entered the medical corps of the regular U S Army in 1920 as a major, in 1924 was appointed physician to the White House by President Coolidge, later by act of Congress was appointed a colonel in the U S Army, resigned in 1929, formerly curator of the Army Medical Museum past president of the International Association of Medical Museums, aged 50, died, January 3, in the Walter Reed General Hospital, of cerebral hemorrhage

David James Gibb Wishart, Toronto, Ont. Canada McGill University Faculty of Medicine, Montreal Que. 1885 emeritus professor of otology and laryngology, University of Toronto Faculty of Medicine, member of the American Laryngological, Rhinological and Otological Society, fellow of the American College of Surgeons, consultant to the department of otolaryngology, Toronto General Hospital and Hospital for Sick Children, aged 75, died, Dec. 5 1934

Ira Hugh Dillon ☉ Topeka, Kan., College of Physicians and Surgeons of Chicago, School of Medicine of the University of Illinois, 1898, member of the American Academy of Ophthalmology and Oto-Laryngology, served during the World War, fellow of the American College of Surgeons, on the staff of the Atchison, Topeka and Santa Fe Railway Hospital, aged 61 died Nov 16, 1934, of coronary thrombosis

Millard Fillmore Jarrett, Fort Scott, Kan., Bellevue Hospital Medical College, New York, 1892, past president of the Kansas Medical Society in 1915 Member of the House of Delegates of the American Medical Association, in 1922 president of the Mid-West Academy of Ophthalmology and Oto-Laryngology, on the staff of the Mercy Hospital, aged 77, died Nov 21, 1934, following an operation on the prostate

Max Lionel Ignatoff, Newark, N J., Tufts College Medical School, Boston, 1926, member of the Medical Society of New Jersey, aged 31, on the staff of the orthopedic clinic of the city board of health, on the staffs of the Crippled Children's Hospital the Presbyterian Hospital, the Newark City Hospital and the Beth Israel Hospital, where he died, Dec. 25, 1934, of chronic nephritis and hypertension.

Allyn Bernard Morse ☉ Shreveport, La., Tulane University of Louisiana Medical Department, New Orleans, 1903, member of the American Academy of Ophthalmology and Oto-Laryngology fellow of the American College of Surgeons on the staffs of the Schumpert Memorial, North Louisiana and Highland sanitariums and the Tri-State Hospital aged 57, died, Dec. 23, 1934 of pneumonia

Alexander McPhedran, Toronto Ont., Canada, University of Toronto Faculty of Medicine 1876 professor emeritus of medicine at his alma mater past president of the Association of American Physicians the Canadian Medical Association and the Academy of Medicine of Toronto on the staff of the Toronto General Hospital aged 87 died suddenly Dec 19, 1934 of pulmonary edema.

Reginald Lloyd Prees, North Fond du Lac Wis., University of Pennsylvania School of Medicine Philadelphia, 1917 served during the World War, past president of the Fond du Lac County Medical Society, president of the board of education and village health officer, aged 43, died, Dec. 19, 1934 in the Veterans' Administration Facility, Milwaukee, of cerebral hemorrhage

Paul Peyton Lane ☉ Wilson, N C., University of Maryland School of Medicine, Baltimore, 1908 past president of the Wilson County Medical Society, fellow of the American College of Surgeons, served during the World War, on the staff of the Moore-Herring Hospital, aged 47, died suddenly Dec. 20, 1934, of heart disease, while on a golf course in Waycross, Ga

Frederick Greene Barfield, Jacksonville, Fla. University of Virginia Department of Medicine, Charlottesville, 1897, member of the Florida Medical Association and the Medical Association of Georgia, served during the World War, aged 61, died, Dec 25, 1934 of cerebral hemorrhage, uremia and nephritis

William Delano Garlock, Little Falls, N Y., College of Physicians and Surgeons, Medical Department of Columbia College, New York, 1881, member of the Medical Society of the State of New York past president of the Herkimer County Medical Society, aged 79, died, Dec. 15, 1934, of heart disease

Chester A Hemstreet, Troy, N Y., Albany Medical College, 1905, member of the Medical Society of the State of New York, on the staffs of the Leonard and Samaritan hospitals, aged 52, died, Dec. 13, 1934, of intestinal hemorrhage following an automobile accident.

William Henry Crook, New Brockton, Ala., Medical College of Alabama Mobile, 1884, member of the Medical Association of the State of Alabama, Confederate veteran, aged 88, died in December 1934 at Bethany, of fracture of the femur as the result of a fall

Jesse H Mitchell, Aoshkie, N C., College of Physicians and Surgeons, Baltimore, 1879, formerly mayor, postmaster and justice of the peace, for many years member of the county board of health and board of education, aged 77, died, Dec. 8, 1934, of diabetes mellitus

Eugene Leo Broeker, St. Louis, St. Louis University School of Medicine, 1911, member of the Associated Anesthetists of the United States and Canada, on the staff of the De Paul Hospital, aged 53, died suddenly, Dec. 24, 1934, of heart disease.

Lee Somerville, North Creek, N Y. Albany (N Y) Medical College, 1899, for many years health officer of North Creek, formerly member of the school board, aged 60, died Dec. 16, 1934, in the Memorial Hospital, Albany, of mesenteric thrombosis

Daniel Calvin Corriher ☉ A Surg, Lieut. (j g) U S Navy, Landis, N C., Emory University School of Medicine, Atlanta 1931 entered the navy in 1931, aged 33, died, Dec. 13, 1934, in the U S Naval Hospital, Washington, D C., of pneumonia.

Thomas Clarke Graves, Memphis, Tenn., Memphis Hospital Medical College, 1894, formerly county health officer on the staff of the Shelby County Emergency and Pellagra Hospital, aged 64, died, Dec. 24, 1934, of carcinoma of the prostate.

Herman Holmes Bogle, Pittsburg, Kan. College of Physicians and Surgeons of Chicago 1893, member of the Kansas Medical Society formerly on the staff of the Mount Carmel Hospital, aged 67, died, Oct. 26, 1934, of peripheral neuritis

Henry Edward Sauer, Miami, Fla., Northwestern University Medical School, Chicago, 1896, at one time instructor in gynecology at his alma mater, for many years on the staff of the Grant Hospital, Chicago, aged 66, died Dec 10, 1934

Christopher S Best, Middleburg, N Y., Eclectic Medical College of the City of New York, 1876, member of the Medical Society of the State of New York president of the board of education, aged 82, died, Dec. 20, 1934, of cerebral hemorrhage

Roy William Merkle ☉ Alton, Ill., Creighton University School of Medicine, Omaha, 1927, formerly city health officer aged 33, on the staff of St. Joseph's Hospital where he died Dec. 23, 1934, of septicemia, following an infection of the finger

Gerhard Hiebert, Winnipeg, Mannt., Canada, McGill University Faculty of Medicine, Montreal, 1900 fellow of the American College of Surgeons, consulting surgeon to the Winnipeg General Hospital, aged 66, died Dec. 25 1934

Edward Randolph Perry, Tacoma Wash. Medical College of Ohio, Cincinnati 1896 coroner served during the World War, aged 62, died, Dec. 19, 1934 in the Veterans' Administration Facility, American Lake, of cerebral hemorrhage.

Hugh Darby Logan, Portland, Ore., University of Oregon Medical School Portland, 1934, aged 26 an intern at the Multnomah Hospital and the Doernbecher Hospital for Children, where he died, Nov. 30, 1934 of pneumonia.

Alfred Wanzer Love, Providence, R. I. University and Bellevue Hospital Medical College New York 1901, member of the Rhode Island Medical Society aged 55, died, Nov. 16, 1934, of myocarditis and coronary thrombosis.

Stephen Benton Elrod ♂ Henryville, Ind. Hospital College of Medicine, Louisville, Ky., 1898, served during the World War, aged 61, died, January 2, at the Norton Infirmary, Louisville, Ky., of heart disease.

Edward Charles Rochette ♂ Worcester Mass., Harvard University Medical School, Boston, 1903, aged 54, died Dec. 13, 1934 in St. Vincent Hospital, of duodenal ulcer, following an operation for subtotal gastrectomy.

Frank Cornelius Leytze, Seattle, Jefferson Medical College of Philadelphia, 1904, member of the Washington State Medical Association, aged 59, died, Nov. 30, 1934, of chronic nephritis and cerebral hemorrhage.

William Hunt Blankenship, Pine Bluff Ark., College of Physicians and Surgeons, Baltimore, 1893 member of the Arkansas Medical Society, aged 68, died, Dec. 12, 1934, of carcinoma of the intestine.

Milford Winslow Rozzell, Hopkinsville Ky., Kentucky School of Medicine Louisville, 1889 aged 77 died, Dec. 10, 1934 at the home of his daughter near Priorsburg, of chronic interstitial nephritis.

George Farwell Dow ♂ Reading, Mass., Harvard University Medical School, Boston, 1896, veteran of the Spanish-American and World wars, aged 65, died, Dec. 9, 1934, of angina pectoris.

Joseph Thomas Hanna, Clugwater, Wyo., Medical College of Indiana Indianapolis, 1881 member of the Wyoming State Medical Society, aged 78, died, Dec. 10, 1934, of cerebral hemorrhage.

Joseph Clement Kochezynski ♂ Hazleton Pa. Medico-Chirurgical College of Philadelphia, 1913 served during the World War, aged 49 died, Dec. 1, 1934, of acute hyperthyroidism.

George Anson Cristler, Hookstown, Pa. Western Pennsylvania Medical College Pittsburgh 1889 formerly member of the school board, aged 82, died, Nov. 27, 1934, of arteriosclerosis.

Peter Harrison Luttrell ♂ San Francisco, Cooper Medical College San Francisco 1908 aged 56 was found dead Dec. 17, 1934, in his automobile of carbon monoxide poisoning.

James Edwin Campbell Taylor ♂ Columbus, Ohio, Ohio State University College of Medicine, Columbus, 1928, aged 35 died Dec. 12, 1934 in the University Hospital of influenza.

John William Jeffries, Mission Texas Marion Sims College of Medicine, St. Louis, 1896 member of the State Medical Association of Texas, aged 73, died, Dec. 12, 1934.

Albert Gordon Hinman, Honeoye Falls, N. Y. Cleveland Homeopathic Medical College, 1903, aged 53 died, Nov. 27, 1934, of hypertension and cerebral hemorrhage.

George W. Webb, Redboiling Springs Tenn. University of Tennessee Medical Department Nashville 1888 aged 86, died Nov. 2, 1934, of carcinoma of the spleen.

Sidney Ray Dannenbaum ♂ San Francisco University of California Medical Department, San Francisco, 1906, aged 53, died suddenly, Dec. 23, 1934, of heart disease.

Charles Chainer Hennin, Springfield, Mass. (licensed in Massachusetts in 1896), aged 61, died Dec. 14, 1934, in the Mercy Hospital, of hypertensive heart disease.

Albert Lafayette Levy, Baltimore University of Maryland School of Medicine, Baltimore, 1903, aged 52, died suddenly, Dec. 29, 1934, of coronary thrombosis.

Samuel Harris Ganser, Chicago Reliance Medical College, Chicago, 1911 aged 48 died, Dec. 23, 1934, of arteriosclerotic myocarditis and pulmonary edema.

Nathaniel Rives Newman, Coxington, Tenn., Vanderbilt University School of Medicine, Nashville, 1899 aged 59 died, Nov. 30, 1934, of hypertensive heart disease.

Edmund T. May, Warthen, Ga. University of Maryland School of Medicine, Baltimore 1885 aged 73 died Dec. 13, 1934 of cerebral hemorrhage and nephritis.

Charles Duane Cobb, San Diego, Calif., St. Louis University School of Medicine, 1904, aged 68, died Nov. 28, 1934, of angina pectoris and coronary sclerosis.

Horace B. Lashlee, Redlands, Calif., Homeopathic Medical College of Missouri, St. Louis, 1877, aged 88, died Nov. 14, 1934, in Beaumont, of arteriosclerosis.

William A. Mathews, Hawkinsville, Ga., Atlanta College of Physicians and Surgeons, 1900, aged 72, died, Nov. 21, 1934, in Thomasville, of heart disease.

Clarence M. Schellinger, Deptford Township, N. J., Jefferson Medical College of Philadelphia, 1879, aged 85, died Oct. 16, 1934, of cardiorenal disease.

Gustavus French Harvey, Los Angeles, Rush Medical College, Chicago, 1876, aged 85, died, Nov. 27, 1934, of hypertension and cerebral hemorrhage.

Frederick Elmer Jones ♂ Brookline, Mass., Baltimore University School of Medicine, 1897, aged 64, died suddenly, Dec. 21, 1934, of heart disease.

John C. Bortorff ♂ Corydon, Ind., University of Louisville (Ky.) Medical Department, 1896, aged 68, died suddenly, Dec. 15, 1934, of heart disease.

Edmund Oliver Hallett, Weymouth, N. S., Canada, McGill University Faculty of Medicine, Montreal, Que., 1883, aged 73, died, Sept. 3, 1934.

Robert Emmett Jones, Philadelphia, University of Michigan Medical School Ann Arbor, 1881, aged 74, died, Dec. 8, 1934, of cerebral embolism.

Daniel Sigler, Elwood Ind. Miami Medical College, Cincinnati, 1874, aged 91, died, Dec. 17, 1934, of bronchopneumonia and mitral stenosis.

Todd R. Boden ♂ McIntyre, Pa., Jefferson Medical College of Philadelphia, 1910, aged 55, died, Dec. 25, 1934, of a self-inflicted bullet wound.

Marion Lee O'Banion, Houston, Texas, Chattanooga (Tenn.) Medical College, 1904, aged 61, died, Oct. 28, 1934, of chronic myocarditis.

Frank M. Tebbetts, Chicago, College of Physicians and Surgeons of Chicago, 1885, aged 70, died, Dec. 21, 1934 of chronic myocarditis.

George Corbin Bryan, Barstow, Calif., Baltimore Medical College, 1896, aged 64, died, Nov. 3, 1934, in Yuma, Ariz., of diabetes mellitus.

Henry W. Johnson, Port Byron, Ill., Hahnemann Medical College of Philadelphia, 1882, aged 80, died, Nov. 25, 1934 of coronary sclerosis.

James Paul Spaekman, Brownsville, Pa. Jefferson Medical College of Philadelphia, 1896, aged 63, died, Nov. 17, 1934, of angina pectoris.

James McWilliam, Toronto, Ont., Canada Faculty of Medicine of Trinity College, Toronto, 1876, aged 81 died, Oct. 11, 1934.

Frank Vanderlip, Brampton, Ont., Canada, University of Toronto Faculty of Medicine 1905, aged 54, died suddenly, Oct. 20, 1934.

Robert Tannahill McNair, Emporia, Va., Medical College of Virginia, Richmond, 1900, aged 56, died, Dec. 9, 1934, of pneumonia.

Henry Francis Strub, St. Louis, St. Louis University School of Medicine, 1926, aged 33, died, Dec. 10, 1934, of heart disease.

Fred Stainsby, Hollyburn B. C., Canada, University of Toronto (Ont.) Faculty of Medicine, 1911, aged 49, died, Nov. 8, 1934.

Mildred Jessie Roberts Broman, Evanston, Ill., Rush Medical College, Chicago, 1916, aged 43, died, January 4, of pneumonia.

Roy White McClintock, Chicago, Harvey Medical College, Chicago, 1904, aged 57, died, January 2, of coronary occlusion.

Henri Trudel, St. Gregoire, Que., Canada, Laval University Faculty of Medicine Quebec, 1878, aged 80, died, Sept. 16, 1934.

John Newhall Kirk, Easton, Pa., Medical College of Ohio, Cincinnati, 1895, aged 61, died, Dec. 3, 1934, of heart disease.

William R. Smyth, Morning Sun, Iowa, Keokuk Medical College, 1896, aged 68, died, Dec. 21, 1934, of heart disease.

Joseph Roach, Baltimore College of Physicians and Surgeons Baltimore, 1891 died Oct. 27, 1934.

Bureau of Investigation

MIN-AMIN

Another Anti-Fat Treatment of the Food-Powder Type

During the past few months a large number of inquiries have come to the Bureau of Investigation asking for information on a preparation sold for the treatment of obesity known as "Min amin." The following letters are typical. From the northwest Dr G H Wahle of Boise, Idaho, writes

Would you kindly inform me by return mail as to the content of a remedy known as Min amin used for reducing weight which is recommended and spoken of by Dr Brady in his writings in the newspapers

From the middle west Dr Don Deal of Springfield Ill, inquires

Min-amin which is recommended by Dr William Brady who has a column of health notes daily in our local paper is made by the National Institute of Nutrition 6777 Hollywood Blvd Los Angeles Calif Several patients have inquired about it and I would appreciate it very much if you would give me the information concerning it

From the southwest Dr Robert M Purdie of Houston, Texas, writes

Do you have any information on Min amin manufactured by the National Institute of Nutrition, Los Angeles California? Appreciate information rationale of its use whether a scientific product etc

From New England Dr Hugo O Peterson of Worcester, Mass, writes

If you have analyzed Min amin a product recommended by Dr Brady for reducing purposes may I have your analysis?

Many other inquiries have come from Nebraska, South Dakota, Minnesota, New Jersey New York, Michigan, Wisconsin, Georgia and other states

The only information regarding the composition of Min-amin that appears on the trade package—and therefore subject to control under the National Food and Drugs Act—is the vague statement that it is "a combination of pure food concentrates containing minerals and vitamins." Women who have written to Dr William Brady, whose syndicated health columns appear in a number of papers throughout the country and have asked how they can safely reduce their weight, have been sent a letter printed in imitation of typewriting under the general head "Personal Health Service." The opening paragraph of this form letter states that excess weight is usually associated with other physical impairments and makes the excellent suggestion that it is wise for the patient to have a complete physical examination by her family physician before entering upon any reduction regimen, followed by a regular check-up at least every week, so that the physician can determine whether the reduction is beneficial. Dr Brady rightly emphasizes the fact that excess weight is usually due to overeating. He then propounds the thesis that fat people overeat "because most good, wholesome food is deficient in vitamins and minerals due to methods of purifying, refining, preserving, storing and cooking or preparing for table" and that hunger is a demand of the body not only for proteins, carbohydrates and fats, but also for minerals and vitamins. As, according to Dr Brady, ordinary food fails to provide such vitamins and minerals, the overweight are led to eat excessively in an attempt to get the lacking accessory food factors.

In the same letter Dr Brady recommends the use of Min-amin and he says

With Min amin which is a concentrate of the essential minerals and vitamins in the proper proportion [Italics ours—Ed] this deficiency of everyday diet is corrected

Dr Brady mentions, too, that if the local drug stores cannot supply Min amin, the recipient can send \$1.50 to the National Institute of Nutrition in Los Angeles and get a two-weeks' supply. In this connection, it is of interest to note that the National Institute of Nutrition is alleged to have been established in June, 1934 and to have been granted permission to issue 4,000 shares of capital stock of no par value. The men behind it are reported to be Drs Llewellyn R. Lewis, John Q. Scroggy and William Brady and Mr J. Frank Brazelton. Drs Lewis and Scroggy are practicing physicians. Dr Brady does not

practice. Mr Brazelton is said to be an X-ray technician in the Hollywood Hospital.

A physician who wrote to the National Institute of Nutrition asking for information regarding the composition of Min-amin received a letter, signed Henry S. Mather, and a sample of Min amin. The doctor was told that a supply of "instruction sheets" for dispensing or prescribing the product would be printed with the physician's name on them if he so desired. He was told too that Min-amin "provides in one product which is palatable a clinically-balanced ration of vitamins from natural sources." The physician also received a twenty-eight-page pamphlet entitled "Nutritional Obesity—Its Cause and Correction." The first chapter, dealing with weight reduction, states in the opening paragraph that reduction of excess weight in nutritional obesity could now "be done with all the assurance of safety, without the use of drugs and with little, if any, self-denial" and that the obese could be given "a practical regime that has been found to be universally applicable." In the same chapter Min-amin was described as "a clinically balanced food supplement containing vitamins." Part of the same thesis already propounded by Dr Brady is dilated on in the pamphlet, namely, that the explanation of nutritional obesity is that the obese eat more food than their bodies require because of an unsatisfied hunger allegedly due to the fact that they are getting insufficient vitamins! As a corollary it is maintained that the obvious correction of nutritional obesity is "a reversal of the process," which can be accomplished by "providing a combination of food concentrates containing vitamins in proper clinical balance."

The only information in the pamphlet "Nutritional Obesity—Its Cause and Correction" regarding the composition of Min amin is found in the chapter entitled "Food and Chemical Analysis." While this gives what is described as a "complete report of our analyses of Min-amin," it does not give any hint as to what Min-amin is. The analysis is given in terms of protein, fat, carbohydrates, fiber and mineral matter. These figures, on a moisture-free basis, read as follows:

	per cent
Protein	21.85
Crude Fat	14.40
Carbohydrates	54.05
Crude Fiber	0.80
Ash (Mineral Matter)	3.00

It also states that the fuel value of a dose (teaspoonful) of Min-amin is 41.84 calories.

An original package of Min-amin purchased direct from the National Institute of Nutrition was turned over by the Bureau of Investigation to the A. M. A. Chemical Laboratory for analysis. A condensed report from the Laboratory follows:

LABORATORY REPORT

"One original package of Min-amin (National Institute of Nutrition, Los Angeles, Calif.) was submitted by the Bureau of Investigation to the A. M. A. Chemical Laboratory for examination. The declared content was 5 oz (approximately 150 Gm.). The package contained a substance having the flavor and general physical and chemical characteristics of a product such as wheat germ or embryo. A microscopic examination disclosed particles which indicated wheat embryo, wheat starch, wheat bran and other parts of wheat in small quantity. The product was also examined by a pharmacognosist who reported that the sample of Min-amin contained wheat germ meal. There were no tissues found except those of wheat. The amount of moisture found to be present was 6.5%.

"Quantitative determinations, calculated to the dry basis, were as follows:

Crude Protein	28.80
Crude Fat	17.14
Carbohydrates other than fiber	48.06
Crude Fiber	1.69
Ash	4.23

"On the basis of protein furnishing 4 calories, fat 9 calories and carbohydrates 4 calories per gram, Min amin has been calculated to furnish 439 calories per 100 grams or 1991 calories per pound. A moderately heaping teaspoonful was found to weigh 7 grams. On the foregoing basis, one heaping teaspoonful would furnish 3073 calories.

"The composition of wheat germ or wheat germ meal varies according to the purity of the germ. References to the literature indicate that the purity of the wheat germ may vary considerably.

"From the foregoing it is concluded that the specimen of Min-amin consists essentially of a relatively pure sample of wheat germ"

It will be noticed that the figures furnished by the exploiters of Min-amin do not altogether agree with those given in the report from the A M A Laboratory. However, the variations may be explained by the fact that commercial wheat germ or embryo is not constant in composition. It probably varies with different types of wheat and even in the same type grown on different soils or under different climatic conditions. Then the degree of refining in the separation of the germ may be a factor. If an appreciable quantity of the starchy part of the wheat remains with the germ, the carbohydrate content will be relatively high and the other components proportionately lower or if the bran particles are not thoroughly removed, the fiber protein and ash content will be increased proportionately to a certain extent.

The closing paragraph of the first chapter of the pamphlet 'Nutritional Obesity' already referred to, explains how to use Min-amin in the reduction of weight. Essentially, the directions are for the obese to eat no breakfast and no luncheon, but to take instead of each of these meals a rounded teaspoonful of Min-amin in an eight-ounce glass of freshly made unstrained orange juice. For dinner, or the evening meal they must eat no breadstuffs, no potatoes, no fats, no sweets, and if a salad is used, it should be made with mineral oil. The obese are told that this regimen does not constitute self-denial.

That persons who follow the instructions that go with Min-amin may reduce weight is doubtless true. That they will have a balanced diet and especially that they will have a diet that will have any particular appeal, seems quite as obviously, untrue. Even if one assumes for the sake of argument that over-eating in the obese is due to a dietary deficiency of vitamins and minerals, it should be patent to anyone who thinks that such alleged deficiencies if present will vary with the diet of the individual. How then, can Min-amin, a powder of supposedly fixed composition contain as alleged, the 'minerals and vitamins in the proper proportion' [Italics ours—Ed.] to correct the alleged deficiencies? Yet this claim is fundamentally the one on which the whole exploitation of Min-amin is based!

At this point it is also worth pointing out that no definite statements are made either in the collateral advertising of Min-amin or on the trade package regarding which vitamins are present nor is there any hint either in terms of recognized vitamin units or otherwise as to how much of each vitamin may be present!

While the argument propounded by those who sell Min-amin that overeating in the obese is due to a lack of vitamins may lend an air of verisimilitude to an otherwise bald and unconvincing tale it is not one that seems to be generally held by students of scientific nutrition. Wheat germ, which is what Min-amin is for all practical purposes is rich in vitamin B. On the Min-amin theory, then, one would be led to expect that the obese had an unsatisfied hunger because of lack of vitamin B in their normal diet. The facts are, however that it is rather generally held that lack of vitamin B in the diet definitely causes a loss of appetite instead of an increase of appetite.

In Min-amin itself there seems to be nothing novel or original. Other food powders have appeared on the market in the past year or two recommended as substitutes for breakfast and luncheon in the treatment of obesity. The one thing about Min-amin that is different is its method of exploitation. Those who sell most treatments for proprietary remedies have to pay newspapers or magazines their regular advertising rates for making the contact between seller and buyer. In the case of Min-amin the thing appears to be reversed. Newspapers that carry—and presumably pay for—Dr. Brady's health column furnish the contact between the sellers of Min-amin and the over-fat buyers! Thus the sellers of Min-amin appear to have solved what to most sellers of proprietaries, is their greatest problem—the tremendous 'overhead' due to advertising costs. Those who put out Min-amin appear to make their contacts through the reading pages (Dr. Brady's health column) instead of through the advertising pages of newspapers, and such reading matter is presumably paid for by the newspapers themselves. This is what seems to make the marketing of Min-amin unique in the field of proprietary products.

Correspondence

TEST OF GLOMERULAR EFFICIENCY

To the Editor —Drs. Edward J. Stieglitz and Alva A. Knight in their preliminary report on "Sodium Ferrocyanide as a Clinical Test of Glomerular Efficiency" (THE JOURNAL, Dec. 8, 1934, p. 1760) gave no credit to the originators of this test when 'presenting a new procedure'.

Erich Lesehke presented it (Histochemische Untersuchungen über die funktion der Niere und Leber, in the *Verhandlungen der deutschen Kongresses für innere Medizin* Wiesbaden, 1914, p. 635, with Bunge). The first time sodium ferrocyanide as a renal functional test was spoken about was by Biberfeld and Basler.

Alois Wolff in reviving this test (Die geschlossene, kaver nose Nierentuberkulose, in the *Zeitschrift für urologische Chirurgie* 6:364, 1921) came to the conclusion that if the kidney function is sufficiently impaired the ferrocyanide salts are still traceable when neither indigocarmine nor phenolsulphonphthalcin are eliminated any more.

GEZA SCHINAGEL, M.D., Detroit.

[This letter was referred to Drs. Stieglitz and Knight, who reply.]

To the Editor —In reply to this note we wish to state that the reference to Lesehke was unknown to us and failure to mention his work of 1914 entirely unintentional. It should be pointed out that prior to the work of E. K. Marshall Jr. (*Am. J. Physiol.* 94:1 [July] 1930), J. G. Edwards (*Am. J. Physiol.* 95:493 [Nov.] 1930) and of Gersh and Stieglitz (*Anat. Rec.* 58:349 [March] 1934) there was no convincing evidence that ferrocyanide salts were excreted solely through the renal glomeruli. The earlier experimental work of Biberfeld and of Basler is discussed in some detail in the paper by Gersh and Stieglitz, to which reference is made in our clinical report in THE JOURNAL. The clinical application of sodium ferrocyanide as a significant test of glomerular efficiency was dependent on the experimental proof of the route and method of its renal elimination. There has been no wish to claim priority for the study of the kidney excretion of ferrocyanide salts, but the clinical application of the recent significant experimental work is original.

ALVA A. KNIGHT, M.D.,
Chicago

TOTAL ABLATION OF THE THYROID

To the Editor —Permit me to express my delight in Dr. Christian's communication concerning total ablation of the thyroid (THE JOURNAL, January 5, p. 64). Doubtless, this letter will create a stop movement in regard to this operation. Dr. Christian's authoritative voice must have a sobering effect on the enthusiasts.

It seems that my paper 'Is Total Thyroidectomy Rational as a Method of Treatment?' (*Canad. M. A. J.*, November 1934), pursuing the same purpose, has appeared timely.

I differ with Dr. Christian on his assumption that the disturbing factors of cachexia strumipriva "will limit the applicability and the effectiveness of this new method of treating cardiac disease to a relatively small group of patients." When one speaks of selection of cases in a general way, it does not mean much. As I pointed out in my paper, so far there is no scientific way of defining such a group of patients. The investigators must work out a strict definition of such a group before offering the operation for general use. Cachexia strumipriva, which cripples the patient for the rest of his life, must be the lesser

evil in such cases. The selection of proper cardiac patients will be a difficult, if not an impossible, task.

Without an elaborate definition of the selected group, every physician will select cases according to his personal views. Under such circumstances the application of the operation will bring immeasurably greater harm than benefit to the people.

O R LOURIE MD, Boston

DYSPNEA

To the Editor—In an article entitled "Dyspnea" published in THE JOURNAL, Nov. 10, 1934, table 2, page 1444, Dr J C Meakins assigns low blood pressure as the cause for dyspnea in insulin shock. The majority of investigators have found that insulin shock is accompanied by an elevation of systolic and a lowering of diastolic pressure, with a consequent increase in pulse pressure. It has been postulated by Cannon and his associates that this effect is due to an increase in secretion by the suprarenals.

MAN WISNIOFSKY MD, Brooklyn

Queries and Minor Notes

ANONYMOUS COMMUNICATIONS and queries on postal cards will not be noticed. Every letter must contain the writer's name and address but these will be omitted on request.

VOMITING IN CHILDHOOD

To the Editor—I have just returned from a call to a well developed boy who will be 6 years old next January. He never had any serious illness or any sickness of any kind until about eighteen months ago. Since then about once a month he has quit playing and goes to his mother complaining of nausea. Soon he begins vomiting, relaxes, turns pale and limber and then his bowels act but not so loose. He goes to sleep rather irritable and after two or three hours wakes up all right and ready for a hearty meal. During the monthly intervals between spells he is just an average natural normal boy except that the father told me he was always hungry and could and did eat as much as he did. I learned in getting a history of the case that I am the sixth physician who has been called to treat him besides a chiropractor, an osteopath and a druggist. All of the physicians are among our best. One was our best pediatrician. None of the physicians who have treated him have done him any good and most of them were honest and frank enough to tell the parents that they did not know what was the trouble with the child. I am writing to you for any suggestions in the way of treatment with this meager information as I saw him today for the first time. I am beginning treatment and study on the theory that an intestinal parasite is the primary cause. Any help you can give me will be appreciated. Please omit name.

MD Texas.

ANSWER.—Vomiting is a common symptom in many disorders of childhood. Noteworthy points about the patient referred to are that he becomes acutely sick at intervals with vomiting associated with pallor, prostration and evacuation of the bowels. He is ill for only a short time and awakens from his sleep feeling well and showing a good appetite. One would think principally of three conditions which might cause these attacks of illness: recurrent or cyclic vomiting, an allergic reaction or overfeeding.

Recurrent or cyclic vomiting is characterized by periodic attacks of vomiting, which continue even if no food is taken. The nausea and emesis last at least for several days. The patients as a rule are greatly prostrated. The breath usually has an acetone odor. In severe cases the liver may be enlarged. The urine shows the presence of acetone bodies, and the blood shows a hypoglycemia. The patient described in the query was not severely ill and the symptoms do not justify a diagnosis of cyclic or recurrent vomiting.

Acute vomiting and diarrhea may result from the ingestion of some food toward which the patient is sensitive or to use an older expression, toward which the patient has an idiosyncrasy. There are many foods toward which patients react in this way, notably milk, eggs, fish, some of the cereals, meats of various kinds, and a great number of other food substances. The patient who manifests these allergic attacks often shows an eosinophilia in the blood as well as in the stools. The sensitivity of these patients may be tested by determining the skin reaction to certain foods or the elimination test may be

employed, which consists of omitting those substance entirely from the diet which are suspected of producing gastro-intestinal symptoms.

Overfeeding may produce indigestion and gastro enteric symptoms that are usually temporary in character, causing not only vomiting and diarrhea but abdominal pain as well.

Obviously, appendicitis may be excluded because of the lack of localized pain and tenderness and the evanescent character of the attacks.

If the patient is to be treated for intestinal parasites, it would be well to confirm the diagnosis either by observing the presence of worms in the stools or by identifying the ova by microscopic examination of the intestinal discharges.

It would seem that the most rational treatment should be directed toward regulation of the diet and the avoidance of overfeeding as well as the use of coarse and indigestible foods. If skin or elimination tests show that the patient is sensitive to certain food substances, they should be eliminated from the diet.

ETIOLOGY OF HYPERTENSIVE DISEASE

To the Editor—In the comment on a book on the treatment of arterial hypertension (THE JOURNAL, September 8 p 779) the reviewer mentions that "logical curative therapy must be based on an understanding of etiology and pathogenesis." Since many physicians have never had an understanding of the etiology and pathogenesis present in the vast majority of cases of primary arterial hypertension will you kindly refer this inquiry to the reviewer with the request that he send me his views on the matter?

WILLARD J STONE MD Pasadena Calif

ANSWER—Adequate presentations of the etiology and pathogenesis of hypertensive disease are to be found in several of the recent American monographs on the subject: Stieglitz, E J. Arterial Hypertension, New York, Paul B Hoeber, 1930; Fishberg, A M. Hypertension and Nephritis, Philadelphia, Lea & Febiger, 1933; Gager, L T. Hypertension, Baltimore, Williams & Wilkins Company, 1930; and Norris, G W, Bazett, H C., and McMillan, T M. Blood Pressure Its Clinical Applications, Philadelphia, Lea & Febiger, 1927.

Briefly outlined, the most acceptable present-day conception of the etiology of hypertensive disease includes two groups of factors: (1) constitutional factors that predispose to hypertension and (2) initiating factors that provoke hypertension. The hereditary influences in the causation of this disease are unquestionably of the greatest importance. Familial hypertension is frequent. Constitutional factors may be operative in a number of ways: by contributing to an intrinsic instability of the whole vasomotor mechanism, by creating an unstable, intense emotional temperament, or by endowing an individual with an arteriolar mechanism poor in endurance (what has been aptly called "poor rubber") and vulnerable to the many factors that may persistently irritate the delicate equilibratory mechanisms of the circulation. It is often difficult to distinguish between purely hereditary or constitutional influences and familial factors that modify the constitution. Bad dietary habits, although obviously not hereditary, may be acquired in early childhood through familial influences.

In persons thus vulnerable, the initiating etiology of hypertensive arterial disease is "anything which persistently creates prolonged arteriolar stimulation." There is no single, common, uniform or invariable etiologic factor for all cases of the disease, nor will one ever be found. There are many who insist that the etiology of hypertension is still entirely unknown because of a failure to appreciate the inevitably large multiplicity of factors involved. The term initiating factors includes such sources of arteriolar stimulation as plumbism, endocrine imbalance and dysfunction focal and other infections, gross and continued dietary indiscretions, chronic arsenic or mercury poisonings, the intoxications of pregnancy, and other factors too numerous to mention. These sources of irritation cause the arteriolar response of hypertonia, with constriction of the vascular lumen and therefore hypertension. If the circulatory apparatus is thus stimulated for but a short time, the physiologic response disappears with cessation of the stimulation. If, however, the stimulation is prolonged, especially in persons made vulnerable through constitutional influences, the progressive changes of hypertensive disease are instituted, and from a state of arterial hypertension the disorder progresses to the arterial disease with hypertension. The mere fact that the causes are difficult of identification and are manifold and frequently superimposed does not justify the contention that hypertension is idiopathic or spontaneous as implied by the term "essential hypertension."

The pathogenesis of the disease is at present fairly well defined. Continuous hypertonia of the arterioles causes hypertrophy of the medial musculature, as convincingly demonstrated by Keith Wagner and Kernohan (Arch Int Med

41 141 [Feb.] 1928) and others. This hypertrophy creates a state of increased sensitivity to stimulation; the arterioles react in an exaggerated fashion to many minor stimuli. With long continued fatigue from continuous hypertonia, exhaustion inevitably follows. As certain smooth muscle cells become exhausted and necrosed, their place is taken by collagenic connective tissue. Thus there is a gradual but persistent evolution of the sclerosing process. It must be reemphasized that the sclerotic changes in the arterioles are the result rather than the primary cause of the hypertension.

TREATMENT OF VARICOSE ULCERS

To the Editor—Will you please describe the best local treatment for varicose ulcers? Please omit name
M D Pennsylvania

ANSWER—Assuming that the leg ulcer in question is truly a varicose ulcer and not a traumatic, thrombophlebitic, syphilitic or trophic lesion, the first step toward a rational treatment is to ascertain the condition of the varicose veins that are responsible for the chronic skin defect. If the deep veins are patent and if the superficial veins do not exhibit any signs or symptoms of a latent or manifest infection, a complete obliteration of the dilated saphenous system is desirable by means of injections of sodium morrhuate or potassium oleate, thereby eliminating back pressure, venous stasis and interference with blood flow through the capillary bed. It may be necessary to do a preliminary high saphenous ligation at the saphenofemoral junction, should the long saphenous vein show valvular incompetence in the thigh. The elimination of the actual cause is the most important factor in bringing about a permanent cure of the ulcer. Should the ulcer however, be acutely inflamed, exhibiting a massive secretion and a phlegmonous wall, a few days of absolute rest in bed elevation and hot boric acid dressings should precede any other treatment.

Locally the ulcer requires an even, elastic snugly fitting support, obtained by Unna's paste boot or an elastic adhesive tape, which is evenly and tightly applied from the toes to the knee. A soft marine or rubber sponge placed above the ulcer site is a soft cushion over a tender area and absorbs some of the secretion. Directly over the ulcer one may place a flat pad of gauze dipped into Unna's paste (zinc oxide, 100 Gm., gelatin, 100 Gm., glycerin 100 cc., water, 200 cc.) If the adhesive dressing is used a mildly mentholated zinc oxide paste can be substituted.

Should the ulcer fail to heal under such management one must consider (1) a disturbance of arterial circulation, evidenced by absent or diminished pulses, drop in skin temperature, dependent rubor and pallor on elevation; (2) the possibility of a nonvaricose ulcer, which may be present with coexisting but incidental veins; and (3) an extensive induration around the ulcer which interferes with the blood supply, or a large sized defect which is not apt to heal spontaneously. Such indurated ulcers may be softened up by injecting rather large doses of 0.5 per cent procaine hydrochloride solution under the base, which procedure may be repeated a few times and is a simple substitute for the undercutting of ulcers. If the defect is too large, small seed grafts placed under the granulations with the blunt end of a Hagedorn needle, will quickly diminish the uncovered area and serve as centers of epithelization. Thiersch grafts usually fail in this location.

When the ulcer is healed, the further objects of treatment must be to prevent recurrence and to soften up the indurated area. Both are usually accomplished by prolonged (from two to three months) applications of an elastic support, again preferably the Unna paste boot. Periphlebitic indurations may yield to small very cautiously applied doses of x-rays.

CELLULITIS OF SCALP AND OSTEOMYELITIS OF THE SKULL

To the Editor—Will you please send me information as to the following: Diagnosis including differential diagnosis of cellulitis of the scalp, subaponeurotic abscess and subperiosteal abscess of the scalp. Treatment and management for these conditions. Information concerning osteomyelitis of the skull resulting from abscess of the scalp especially as to how long a period is required for its development.

WILLIAM O. McLANE, M.D., Jackson, Minn.

ANSWER—Cellulitis and erysipelas are common on the scalp and have the same characteristics as elsewhere. There is usually a brawny edema of the skin and there may be great edema of the eyelids and face. Usually wet dressings are used until pus forms.

A subaponeurotic abscess is usually quite serious. Here the pus spreads widely and may point in the neighborhood of the eyebrow, the temporal crest, the zygoma or the occiput. It is usually associated with infected wounds or disease of the cranial

bones. One or more incisions should be made in the regions where the pus appears to be pointing, with avoidance of injury to nerves and blood vessels.

A subperiosteal abscess is nearly always associated with injury or disease of the cranial bones. It is limited to the bone affected, but there may not be necrosis of the bone. Prompt incision should be made. In case of specific streptococcal infection, serum may be used as in erysipelas.

Abscess or infection may be in contact with the bone for some time without necrosis, but early incision should be made to avoid osteomyelitis. The time varies as well as the virulence of the infection. The staphylococcus is the most common organism present in both regional and metastatic infections. In the treatment, osteomyelitis should be treated as if in the long bones, that is, adequate drainage, removal of dead bone, cleansing of the wound and wide drainage.

In the differential diagnosis, several conditions should be considered. Superior longitudinal sinus thrombosis may produce edema and congestion of the scalp. There may be cortical anesthesia, ankle clonus and increased knee jerks, with local tenderness or even small abscesses.

Extradural abscess or local leptomeningitis may be associated with a hard, puffy, tender, local swelling known as "Pott's puffy tumor" over the scalp at the site of the abscess, the result of edema. Focal symptoms may be present.

A hematoma may be present, above the aponeurosis, beneath it, or under the pericranium. Hematomas are of significance only in that they may be the result of grave injury to the skull and brain underneath.

Cystic and solid tumors may occur. Sebaceous cysts are common and, when they ulcerate, are called Cock's peculiar tumors.

Dermoid cysts occur near the anterior or posterior fontanel, at the root of the nose near the occiput, at either angle of the orbit, near the ear, or in the temporal region. They are often closely attached to the bone.

Simple serous cysts or meningococles are seen near the sutures of the skull.

Aneurysms are easily diagnosed by the evidence of their vascular nature.

Nevi and adenomas are not uncommon on the scalp.

A cephalhematocoele is a rare tumor formed of cavernous venous spaces in the scalp communicating through the bone with the superior longitudinal sinus.

Papillomas may resemble a horn or wart.

Lipomas are rare on the scalp.

Plexiform neuroma may form a pendulous growth.

Sarcoma of the scalp usually extends from the bone underneath.

Neitheloma may arise, from a wart, a scar or an ulcerated sebaceous cyst.

Pneumatocoele may arise from the sinuses after injury.

Chronic infections from gummatous osteomyelitis, tuberculosis or actinomycosis together with many other conditions may be diagnosed from biopsy or laboratory tests together with a history and careful general examination.

DENTAL DECAY IN A CHILD

To the Editor—I have a patient, a girl 10 years of age who has lost three permanent molars within the last six months because of crumbling followed by decay. She appears to be a normal healthy child and her only visible abnormality is that she is about 20 pounds (9 Kg.) over weight weighing about 88 pounds (40 Kg.). She is a member of one of the better families and has a nourishing diet and takes excellent care of her teeth. I have thought of a lack of vitamins and have given her various cod liver oil and haliver oil preparations. I also am trying to reduce her weight to normal by a simple reduction in diet. Any advice you can give me to arrest the brittleness and crumbling of this child's teeth will be greatly appreciated.

F. CLAUDE BEDSAUL, M.D., Floyd, Va.

ANSWER—Brittleness and crumbling followed by decay of the molars of a 10 year old child can be interpreted only as a type of decay beginning in deep pits and fissures of the enamel of the occlusal (chewing) surfaces of the teeth. This form of decay usually penetrates the enamel through a small opening and spreads rapidly through the dentin, undermining the enamel crown and causing it to become brittle and to crumble. Dentin containing many interglobular spaces, undercalcified zones, is considered to be associated with rickets, a disease that is likely to occur at the same time as the development and calcification of the first permanent molars. After the teeth are fully formed and erupted, little can be done to change their character or to harden the enamel or improve the quality of the dentin. Vitamin D administered at the time of the formation of the teeth affects the process of calcification favorably but appears to have little or no effect in this sense after eruption. Even

though it is stated that this girl has a nourishing diet, the fact that she is overweight and susceptible to tooth decay warrants a careful investigation of her dietary habits. In spite of frequent statements to the contrary, as far as known there is no specific dietary deficiency involved. Yet caries is much more likely to be found in children whose carbohydrate intake is high, especially the highly refined forms of sugars and starches, and whose protein, mineral and vitamin consumption is low. Proper management of such cases has to do not only with increasing the intake of the preceding and rigidly limiting carbohydrates to energy requirements but also prompt recognition and immediate treatment of the initial lesions of caries by the dentist. Some foods that require vigorous chewing should be eaten at each meal, and each meal should be concluded with uncooked fruit or fruit cooked with a minimum amount of sugar, or some similar dessert instead of cake and highly sweetened pastry. Candy and food between meals should be prohibited. It would be advisable to have her dentist fill all deep pits and fissures in the molars as soon as these teeth are fully erupted (Hyatt's method). In children susceptible to dental decay, wholly successful management is difficult of attainment.

CHRONIC GLOSSITIS

To the Editor—I have a patient who has a sore tongue, also the surrounding mucous membrane of the mouth is sore. It is red. The tongue is clear of a membrane and is not coated. The patient had a very severe grade of secondary anemia which is now improving under treatment. Will you kindly state the possible etiology and treatment for this condition?

J S DUNCAN M.D., Gary Ind

ANSWER—The description of a chronic red tongue and redness of the adjacent oral mucous membrane with great soreness, is suggestive of a chronic disease of the tongue known as Moeller's glossitis. The best article on this is by F G Harris (*J Cutan Dis* 33 742, 1915). The etiology in most cases is obscure. Most of Moeller's cases were in persons having intestinal worms, but Harris's cases and those reported by others did not present such infestation. Engmann and Weiss (*Arch Dermat & Syph* 1 119 [Feb] 1920) reported a case in which endamebas were found in tooth abscesses. On extraction of the teeth and treatment with emetine, the patient recovered.

Zinsser (*Handbuch für Dermatologie und Geschlechtskrankheiten* 14 101) states that all cases of Moeller's glossitis are due to pernicious anemia. While his statement finds little support in the case histories of Moeller's glossitis, his advice, that in all such cases the blood should be carefully studied and watched for a long time, is certainly good.

The patient's own experience as to diet may be safely followed, avoiding foods that cause pain, except in severe cases, in which all foods cause pain. Attempts to anesthetize the tongue before meals may then be made, using phenol in glycerin 5 per cent or stronger or orthoform powder on the tender areas, rinsed off before eating. Sharp tooth corners should be smoothed down. All foods should be soft.

Röntgen treatments are said to relieve the pain temporarily. They should be kept below the erythema dose. Use of ultra-violet radiation is also credited with temporary relief of pain.

Hutter, Middleton and Steenbock found that rats (Vitamin B Deficiency and the Atrophic Tongue, *THE JOURNAL*, Oct 21, 1933 p 1305) after about thirty-nine days on a diet deficient in vitamin B₂ lost the normally very sharp papillae of the tongue leaving a smooth dorsum much like that of the atrophic tongue of man. When vitamin B₂ was supplied, the papillae reappeared and the tongue appeared normal. They therefore suspected that vitamin B₂ deficiency might have some relation to the atrophic tongue. Their effort to cure such tongues by diets rich in vitamin B, however, were not successful enough to be convincing. Tomato juice or yeast by mouth and liver extract intramuscularly could be tried in the case under discussion if this has not already been done.

LEMON WITH FISH AND CHEESE WITH PIE

To the Editor—I Can you enlighten me through the columns of *THE JOURNAL* as to the origin and the significance if any of the custom of serving a slice of lemon with fish. I have wondered whether it originated or was connected in some way with the issuance of fresh lime juice to British seamen after its discovery as a preventive of scurvy. 2 What was the origin of serving cheese with apple pie? Please omit name.

M D California

ANSWER—1 The custom of serving lemon with fish probably originated in Italy and other southern countries where lemons grow abundantly. All the natives of these countries use lemon juice on almost every food they eat. They put it

on most of their vegetables, on shell fish and on fish and fowl. This is probably the most logical place where this custom may have originated.

2 The custom of eating cheese with pie may have originated with the Italians eating home-made cheese with apples and pears. Then they started using such cheese as either Parmesan ungrated, in whole pieces, or Bel Paese with raw fruit. The British took up the custom of using raw fruits instead of stewed fruits in their deep dish pies and with it served a piece of cheese as the Italians had done. The custom was probably brought to the United States, particularly the New England states, where the cheese used was the local store cheese or American cheese.

THROMBOPHLEBITIS IN INJECTION OF VARICOSE VEINS

To the Editor—A woman has a thrombophlebitis in one of the varicosities of the leg. How long should one wait before using the injection method of treating the other varicose veins? Would it be correct to go ahead on the well leg while waiting? Kindly describe the technique of determining the patency of the deep veins. Please omit name.

M D New Jersey

ANSWER—The correspondent does not state whether the patient has a deep or a superficial thrombophlebitis. Assuming that the infection is only in the previously dilated saphenous vein, it is wise to wait until all signs of local inflammation, such as redness, hardening of the wall of the vein, and increased skin temperature as compared with the unaffected side, have disappeared. It might also be advisable to look for the source of infection in the tonsils, teeth and cervix. There is no arbitrary period for starting the injections, but it takes usually from six weeks to three months before the injections may be safely given. In such a case it is wise to use small provocative doses of the sclerosing solution, not more than a few drops at a time and observe the inflammatory reaction following such a minute injection. If the veins of the other leg seem entirely free from infection, one can cautiously proceed with treatment on that side. However, it must be borne in mind that injections on the unaffected side may light up the subsiding process on the affected side.

The patency of the deep veins is determined by the test of Perthes. Following the constriction of the saphenous trunk by a towel, the patient is asked to flex and extend the knee vigorously ten times. During the exercise, blood is sucked into the deep veins and the superficial varicosities collapse. When the pressure of the towel is released, the filling from above demonstrates the amount of blood expressed into the deep veins. If the deep veins are not patent or if there is a deep venous valvular insufficiency, no diminution of the superficial veins will take place.

MULTIPLE MISCARRIAGES

To the Editor—Will you please advise me regarding the proper procedure in the following case. A normal appearing woman aged 26 started menstruation at 13 years. The normal cycle continued until six years ago then she would menstruate one week pause one week then menstruate again. With the onset of the irregular cycle dysmenorrhea occurred. She has been married five years and has been pregnant twice miscarrying at three months. The basal metabolic rate is 16+. Her sister has been pregnant twice with hyperemesis gravidarum and in spite of late hospitalization in both instances no procedures were successful except emptying of the uterus. How can I arrest another miscarriage? Both women are anxious to be mothers. Please do not use my name.

M D Illinois

ANSWER—The onset of dysmenorrhea after a few years of painless menstrual periods may have its origin chiefly in the psyche or in an adenomyosis of the uterus. Either cause may be difficult to determine. The mental reaction of the patient may be determined after a number of conversations. Adenomyosis or endometriosis of the uterus can be diagnosed with certainty only by means of an examination of the entire uterus. Microscopic examination of curetted material does not often help. However, clinically a diagnosis may often be made by the presence of atypical bleeding severe dysmenorrhea that appears after a long period of painless periods, and a sign recently pointed out by Halban namely, a marked cyclic enlargement of the uterus in the premenstrual phase of the period. The uterus diminishes in size immediately after the menstrual flow ceases.

Repeated miscarriages are often difficult to prevent. Occasionally careful macroscopic and microscopic examination of the expelled products of conception throws some light on the cause of the miscarriages. Recent work has shown that estrogenic substance stimulates uterine activity and that its antagonist, the hormone of the corpus luteum, inhibits the muscular activity of the uterus. Hence estrogenic substance

is advocated not only for cases of dysmenorrhea due to spasmodic contractions of the uterus but also for cases of threatened abortion and habitual abortion when no apparent cause can be detected. A prescription that has seemed to help some women is the following:

	Gm or Cc	
R _x Red mercuric iodide	añ	0.065 gr.
Arsenic trioxide		12 S iii
Ferrous carbonate		
Mix and make sixty capsules		
Sig One capsule three times a day		

Patients with hyperemesis gravidarum should be placed in a hospital early in the course of the illness and treated energetically along the customary lines. When hypodermoclysis, proctoclysis, sedatives and other drugs fail to stop the vomiting, duodenal feeding usually accomplishes the desired result.

POLYNEURITIS IN MONOTYPE CASTING

To the Editor—I have a patient who for the last five years has been employed as a monotype operator. Six months ago severe neuritic pains suddenly developed in both arms and persisted for weeks. This condition was followed by muscular atrophy. I first saw him last week. He gives a history of having an exfoliation of the skin over both hands a few weeks after the onset. What can be done to determine the cause of the polyneuritis? Can you refer me to any literature concerning polyneuritis as an occupational disease in monotype work? Please omit name and address.

M D Illinois

ANSWER—There are two processes in monotype casting. The first is the striking off of symbols on a keyboard, which work is similar to typewriting; the second is the use of these strips of paper produced by the keyboard machine, which are fed into the caster and serve as molds for casting the type. In some machines the two operations are combined.

There is no hazard in the first part of the process beyond the possible overuse of the hands and arms in typing. In the second part of the process there is a distinct lead hazard, although this is not a severe one. However one would expect the form of neuritis to be an extensor paralysis resulting in wrist drop if lead was the important factor.

In order to determine the possible toxic effect of lead in the case outlined the usual tests for lead poisoning should be tried.

(a) Examination of the blood for stippling, polychromatophilia and secondary anemia.

(b) Examination of the urine for lead to determine whether or not there is more than 0.05 mg of lead per liter, and whether hematuria is present.

(c) Examination of the patient for other symptoms of lead poisoning such as the lead line of the gums, constipation, abdominal pain, wrist drop and foot drop.

The dangers of lead poisoning in monotype casting are described in *Industrial Poisons in the United States* by Dr. Alice Hamilton in which there is also a discussion of lead poisoning. More recent information on lead poisoning appears in *Industrial Toxicology* by the same author, published by Harper & Brothers in 1934, which contains an excellent bibliography.

CHRONIC DUODENITIS

To the Editor—I have under my care at the present time a patient who has had a gastric ulcer during the past six years. At the present time his symptoms are the same as those of a bad ulcer case. Complete examination of the stomach, intestine and gallbladder has shown that the ulcer area is healed and that all the trouble lies in the duodenum, the diagnosis by roentgenologists being duodenitis. I find nothing in my books on the treatment of this condition. I might say in passing that the usual ulcer treatment brings absolutely no response in this patient and alleviates none of the symptoms of which he complains. Can you suggest any mode of treatment that might produce an eventual clearing up of this condition? I have been tempted to try Synodal and also feeding through a duodenal tube that has passed below the duodenum. What are your opinions of these ideas and their possibilities?

AVERY D. POWELL, M.D., Atica, Ohio

ANSWER—Alcohol, tobacco, spices and carbonated drinks should be strictly avoided in the treatment of chronic duodenitis. Elimination of foci of infection in the teeth, tonsils, paranasal sinuses, gallbladder, appendix and prostate should be attempted. Stomach secretions should be regulated with the use of alkalis if hyperacidity is present, and with dilute hydrochloric acid if a hypochlorhydria is found. Atropine is used to control spasm and irritation. Bismuth subnitrate alone or with alkali is used for its soothing effects. The instillation of silver salts or irrigation and lavage may be attempted with the duodenal tube. If symptoms persist surgical intervention is necessary. A pyloroplasty after the method of Judd and Nagel, may be the method of choice. Synodal is a proprietary preparation given intravenously while the results reported have been enthusiastic; the evidence available is hardly such as to indicate extraordinary merit.

CONGENITAL EXTRA LUMBAR VERTEBRAE

To the Editor—Please send without delay all information pertaining to congenital extra lumbar vertebrae (sixth lumbar) and especially as regards traumatism to the back when this condition is present.

FLOYD G. PATTERSON, M.D., Du Bois, Pa.

ANSWER—The occurrence of six lumbar vertebrae is a fairly common condition.

Whether the sixth lumbar vertebra predisposes the back to additional trauma is controversial. The condition is usually found incidentally (or accidentally), that is, when films are made of the spine incident to the study of nearby tissues, and roentgenographic studies follow an accident to the lumbar area.

In a discussion of numerical variations of the spine, Stender (Diseases and Deformities of the Spine and Thorax, St. Louis, C. V. Mosby Company, 1929) states that in the lumbosacral section one finds a caudal assimilation consisting in sacralization of the fifth lumbar in various degrees, ranging from a large, bifid transverse process to complete sacralization of the fifth lumbar segment; the cranial assimilation consists in lumbarization of the first sacral vertebra whereby the number of lumbar vertebrae is increased to six, while that of the sacral segment is decreased to four.

Boliart reported approximately 44 per cent of anomalies and anatomic variations in 1,000 symptomless spines.

In the routine examination of 931 symptomless spines of industrial employees, Cushway and Maier found twenty-five instances of six lumbar vertebrae.

Gadow (Evolution of the Vertebral Column, Cambridge University Press, 1933) states that the rhinoceros has four lumbar vertebrae, the zebra six lumbar vertebrae and *Equus Przewalski* six lumbar vertebrae.

PILONIDAL CYST

To the Editor—Can you tell me whether there is any preparation that will close in a pilonidal cyst? I have used Beck's paste with fair results but have been unable to close it entirely. This patient absolutely refuses to be operated on. Please omit name.

M D New York

ANSWER—It is probable that some sclerosing agent might obliterate the pilonidal cysts or sinuses, but no reports of the successful use of any have been seen. The lining must be completely destroyed or removed.

SYPHILIS LATE IN PREGNANCY

To the Editor—The patient is five months pregnant and has a 4 plus Wassermann reaction. When she was seen five years ago with a secondary eruption, she received one course of neoarsphenamine and mercury. She is unusually sensitive to neoarsphenamine. A recent attempt on two occasions to give even small doses of this drug caused marked vomiting for twenty-four hours. Would you consider intramuscular injections of bismuth compounds biweekly for the remainder of the pregnancy sufficient therapy to produce a normal fetus? If not, what additional therapy is recommended in such a case? I would appreciate your advice. Please omit name.

M D New York

ANSWER—Intramuscular injections of bismuth compounds for the remainder of the pregnancy will most likely not be sufficient to guarantee the birth of a healthy baby. The placenta at the present stage of gestation is fully developed and it will require neoarsphenamine to destroy the spirochetes in this organ. While bismuth compounds will have a deleterious effect on the spirochetes in the placenta, neoarsphenamine is much more potent in destroying them. In spite of the patient's sensitivity, neoarsphenamine should be administered. Before each injection of arsphenamine it is advisable to give calcium gluconate intramuscularly and atropine. The dose of arsphenamine should be 0.15 Gm and should be given slowly with the patient lying down. The patient should remain lying down for one or two hours after each injection. It is best to alternate a few injections of arsphenamine with a few injections of a bismuth compound and continue this to term.

HISTAMINE IN SEASONAL URTICARIA

To the Editor—I should like to know something about the use of histamine injections in the treatment of seasonal summer urticaria lasting about two months, a number of skin test reactions being positive.

CORNELL G. GRAY, M.D., Hanover, Pa.

ANSWER—Search of the literature dating back to the time when histamine began to play a part in the discussions of allergic conditions has failed to reveal any article dealing with the use of histamine injections in the treatment of seasonal

urticaria or any other form of urticaria. There is, however, some work on the treatment of bronchial asthma by injections of histamine.

In this article, by Ramirez, the injections were begun with small doses and increased much as pollen extracts are increased, although in each case there came a point at which constitutional reactions characteristic of histamine poisoning resulted. These symptoms consist of prostration, perspiration and other less well marked changes and Ramirez decided that the treatment of asthma by histamine injections was not successful.

Histamine has also been used by Skouge (Percutaneous Histamine Therapy, *Nord med tidsskr* 6 1252 [Oct 21] 1933) in the treatment of various forms of rheumatism myalgia neuralgia, varicose ulcers, furuncles and arsphenamine infiltrations, with complete relief from pain in about 80 per cent of the cases, the results here were sometimes temporary.

IRIDOTASIS—IRIDENCELEISIS

To the Editor—What is the origin of the terms iridencleisis and iridotasis? It may be well understood as to what these operations on the iris are but very few know why these terms are selected and no dictionary or work on ophthalmology gives the derivation of them.

H W Wonnkuff M D Joliet Ill

ANSWER.—Iridotasis is evidently a simplification or corruption of "iridodesis," the name of the old operation for attaching a portion of the iris into an opening in the cornea. The word is derived from the Latin noun *irido* plus the Greek *deiosis* meaning a binding.

The origin of iridencleisis is not perfectly clear. It is probably derived from the Latin noun *irido* or *iriden* (combining form) and the Greek *κλειστός* meaning "closed," "enclosed" or "included." The combination denotes the 'iris enclosed or included in the wound'.

CHRONIC CYSTIC MASTITIS

To the Editor—A woman aged 39 married with two children whose family and past histories are negative had an enlargement of one breast five months ago which became painful. The pain shortly after subsided and disappeared. At present the breast is soft. The size and appearance of the nipple are the same as of the other breast. There are no dimples or any other signs. The enlargement however though not increasing still persists. Her general health is good. Please advise diagnosis and treatment if any. The woman is neither pregnant nor nursing. Please omit name.

M D New York

ANSWER.—Such an enlargement of the breast may be similar to chronic cystic mastitis, which is now believed to be the result of a disturbance in the female hormones. Such changes in the breast may cause either hyperplasia or cystic changes in either one or both breasts. In the absence of any further changes indicative of some other condition, no treatment of the breast is indicated. Examination of the pelvic organs might be in order.

ALBUMINURIA AFTER SCARLET FEVER

To the Editor—A boy aged 10 years had scarlet fever ten months ago. The attack was mild and convalescence uneventful except that he has continued to have 1+ albumin in the urine. I should like to know the prognosis as to this albuminuria and just how strict I should be as to his diet and exercise. Kindly omit name.

M D Texas

ANSWER.—In the absence of blood and granular casts, the prognosis should be good. As a rule little restriction in diet is necessary for a case of this kind. The patient will frequently do well on a high protein diet. Should edema develop, a salt free diet ought to be instituted.

LOCAL ANESTHETIC FOR TONSILLECTOMY

To the Editor—Have you any information regarding the use of nupercaine for injection for local tonsillectomy in a patient who has had aggranulocytic angina? I should like to know as soon as possible if it would be safe to proceed using nupercaine. The patient is in fair physical condition—the white count is 7,200—but he has a myocarditis which has kept him from work.

A L LINGHURST M D Elgin Ill

ANSWER.—We have been able to find no unfavorable reports regarding the use of nupercaine. If the patient is otherwise in condition to be operated on the use of this preparation for local tonsillectomy should be perfectly safe. If there is any doubt regarding its use the employment of 1 per cent procaine hydrochloride by the nerve blocking method would be devoid of risk. The procaine solution in ampules has incorporated in it about 1 20000 epinephrine giving a perfect anesthesia without any edema so that the line of cleavage may easily be found.

Tennessee October Examination

Dr H W Qualls, secretary, Tennessee State Board of Medical Examiners, reports the written examination held in Memphis Oct 1-2 1934. The examination covered 8 subjects and included 80 questions. An average of 75 per cent was required to pass. Nineteen candidates were examined, all of whom passed. The following schools were represented:

School	PASSED	Year Grad	Number Passed
Harvard University Medical School	(1933)		1
St Louis University School of Medicine	(1934)		1
University of Tennessee College of Medicine	(1934 17)		17

Five physicians were licensed by endorsement from September 15 to October 25. The following schools were represented:

School	LICENSED BY ENDORSEMENT	Year Grad	Endorsement of
College of Medical Evangelists (1930) N B M Ex	(1929)	California,	
Kentucky School of Medicine	(1906)	Kentucky	
Woman's Medical College of Pennsylvania	(1932)	Ohio	
Medical College of Virginia	(1933)	Virginia	

Vermont Endorsement Report

Dr W Scott Nay, secretary, Vermont State Board of Medical Registration, reports 7 physicians licensed by endorsement from Aug 6 to Oct 9 1934. The following schools were represented:

School	LICENSED BY ENDORSEMENT	Year Grad	Endorsement of
Johns Hopkins University School of Medicine	(1931)	N B M Ex	
Tufts College Medical School	(1932)	Mass

Book Notices

The Autonomic Nervous System By Albert Kuntz Ph.D. M.D. Professor of Micro Anatomy in St. Louis University School of Medicine Second edition Cloth Price \$7.50 Pp 097 with 73 illustrations Philadelphia Lea & Febiger 1934

The topics presented in this valuable book include the morphology and distribution of the autonomic nervous system, the structure of the ganglion cells, the central autonomic centers and conduction pathways the physiology of the autonomic nervous system, the development of the autonomic nervous system the innervation of the heart, the blood vessels, the respiratory system the digestive tube, the hiliary system the glands, the urinary organs and the sex organs, the involuntary innervation of the eye, the autonomic innervation of skeletal muscles, the pathology of the autonomic nervous system, visceral sensitivity and referred pain, autonomic imbalance, the autonomic nervous system in disease, and the surgery of the autonomic nervous system. The author does not say for whom this book is intended, but it is clear that all who are interested in this vital subject which assiduous laboratory and clinical research is gradually lifting from darkness into light and which is daily being correlated with banal but little understood visceral phenomena and with the unfolding panorama of diseases of the autonomic nervous system, will find in it a vast store of information arranged in orderly and available fashion. The reader may be somewhat awed by the first chapter, on the morphology and distribution of the autonomic nervous system, for here a master anatomist throws him unceremoniously and headlong off the deep end. If the reader will persevere, however he presently launches into the body of an admirably clear and concise work. The histologic discussions particularly are beautifully illustrated and are worthy of unstinted praise. To orient oneself anew with respect to any phase of the autonomic nervous system is, to say the least, a time consuming task and requires access to a library well stocked with current periodicals. The author has succeeded commendably in culling what appears to be of greatest importance and reliability, and in turning the various facets of the subject to the reader in well balanced relationship for his inspection and deliberation. Unfortunately many problems to which one would like to know the answers are as yet unsolved, but when this is the situation, the reader wishes to know this also. Such problems as the autonomic innervation of skeletal muscle, still hotly disputed, are presented with fairness, restraint and understanding. Various captions in the chapters are clearly indicated, the whole work is carefully indexed, and any information sought may instantly be found. A bibliography of 117 pages tells the reader where he may carry on his search should this be desired.

Diffuse Sclerosis (Encephalitis Perilaxialis Diffusa) By L. Bouman M.D. Professor of Psychiatry and Neurology Utrecht University Cloth Price \$5 Pp 160 with 64 illustrations Bristol John Wright & Sons Ltd. 1934

Diffuse sclerosis, also known as Schilder's disease and under many other names, has attracted much attention during the last twenty years, though it has been known for more than fifty years. Strümpell for instance, mentions it even in the oldest editions of his textbook, but the pathologic basis was first emphasized clearly and properly by Schilder. In diffuse sclerosis a vast destruction of the subcortical white substance mainly of the occipital and temporal lobes, takes place, producing a clinical picture that can sometimes be diagnosed at the bedside. Blindness, and deafness setting in acutely or subacutely, combined with speech, motor and often psychic disturbances are the frequent symptoms and signs. In many cases, however, neither the clinical nor the histopathologic picture is characteristic enough to enable one to make a correct diagnosis. Nor is it always possible to make a definite diagnosis post mortem as the main histopathologic feature, demyelination (loss of myelin) in the white substance of the central nervous system, occurs also in multiple sclerosis, postvaccinal encephalitis, a number of hereditary and familial nervous diseases neurosyphilis and many other conditions. The foregoing features are all carefully discussed by Bouman on the basis of his personal experience and the study of the literature. Though the review

is down to the present and the subject is covered fully, no definite answer is given to such problems as whether diffuse sclerosis possesses specific clinical or pathologic features and whether it can safely be differentiated from similar conditions. As a matter of fact, the part of the monograph dealing with the microscopic changes of diffuse sclerosis is obscure. It is largely made up of quotations of various opinions, mostly confusing and misleading. The book would be much more valuable if these unnecessary and obscure histopathologic discussions (pp 124-142) had been omitted. Another distracting feature is the abundance of quotations in original German and French and the frequent use of German words whenever the author had difficulty in finding a suitable equivalent in English. The book is beautifully printed and the illustrations are for the most part clear, but the price is decidedly out of proportion to the size and the general merits of the monograph.

Developmental Anatomy A Text Book and Laboratory Manual of Embryology By Leslie Brainerd Arey Robert Laughlin Rea Professor of Anatomy Northwestern University Third edition Cloth Price \$6.50 Pp 593 with 547 illustrations Philadelphia & London W B Saunders Company 1934

With all the changes of recent editions, the main feature of this book is the presentation of developmental processes from a three dimensional point of view. This can be referred back to the extensive dissections of embryos by C. W. Prentiss, on whose book this one was originally based. The value of the method stands out particularly in the chapters on the coelom, the mesenteries and the heart. The original emphasis on points of practical value to the medical student and practitioner is maintained with a corresponding stress on abnormal development. The laboratory manual remains substantially as it was, the sections on general embryology and organogenesis have been thoroughly revised and some new figures added. The author's method of documenting his statements by references to the original literature is helpful to the teachers and the very few students (cheul) who are interested in the evidence on which the general conclusions are based. The account of the physiology of the female reproductive system is judicial, although the task is a difficult one because of the rapid accumulation of data in recent years and the numerous conflicts of opinion on fundamental questions. Fetal age and the duration of pregnancy are given the space they deserve. The illustrations are the most conservative feature of any textbook, for it is expensive to change them. In the chapters on the development of the external form and the brain, the retention of various old illustrations is to be regretted. The latter chapter suffers more than any other from a lack of first-hand knowledge of the material. The chief practical value of a study of brain development at present is the establishment of landmarks for reference in the adult brain. This has not received adequate emphasis, nor has the value of morphogenesis in unraveling the intricate relations in the fore brain been fully exploited. There is little else to criticize. The illustrations of sex differences in the external genitalia of young embryos are misleading, since they represent exceptional conditions that have proved to be inadequate for diagnosis in some cases at least. In figure 195 it is hardly apparent that in early stages the mesonephros extends through most of the thoracic region and the pronephros is almost entirely confined to cervical levels. Typographic errors are rare and never serious. It is gratifying to see that the price has not been increased despite the enlargement of the book.

Technique du traitement des fractures Par Lorenz Böhler directeur de l'Hôpital des accidentés Vienne Traduction d'après la quatrième édition Par M Boppe chirurgien des hôpitaux de Paris Préface du Professeur Hartmann Cloth Price 160 francs Pp 652, with 1,046 illustrations Paris Masson & Cie 1934

This is a translation of the fourth edition of Böhler's book, which originally appeared in German. The mechanics of fractures and the displacement of the fragments are illustrated in a way that even the beginner can understand. The author illustrates to a high degree the value of skeletal traction, in the popularization of which method he has occupied so important a place. He describes in detail the method of local anesthesia in the treatment of fractures and dislocations, a method that owes its popularity to his pioneer work. It is noteworthy that in the treatment of fracture of the neck of the femur by

the Whitman abduction method, the assistant is obtaining internal rotation of the leg by turning the foot and ankle. This is a mistake, because the internal rotation should be done above the knee in order to spare the delicate structures of the knee from the trauma due to the twist and rotation that is necessary when internal rotation is accomplished by turning the foot and ankle. Illustrations 143 and 144 on the circulation of the carpal scaphoid are highly instructive. The Beck method of perforations in the treatment of pseudarthrosis is described and illustrated. The English reading surgeon will be interested in what this edition has to offer over the original German and small English translation, which has been off the press for about four years. A careful comparison discloses that the French edition has nothing to offer in addition. Again Steinberg, the translator of the first German edition, is to be highly complimented. While the English edition has 234 illustrations and the French edition 1046, it does not seem worth the difference in price.

Maternal Mortality in Philadelphia 1931-1933. Reports of Committee on Maternal Welfare. Philip F. Williams M.D. Chairman. Paper. Price \$1. Pp 143 with illustrations. Philadelphia: Philadelphia County Medical Society 1934.

This is packed full of valuable information regarding maternal mortality in a large city. A proper review of it would require many pages. The study was conducted on the lines pursued by the committee of the Academy of Medicine of New York in 1933, thus making the two results comparable to some extent. As always with statistical studies it is impossible to find a common ground, common definitions and complete (if not biased) original entries. It is stated that while the birth rate in Philadelphia during the last thirteen years has dropped from 41,343 to 30,753, the maternal death rate has had no reduction, yet a table reads that the death rate was 6.3 in 1932 and 4.4 in 1933 per thousand total births. There has been a decrease in deaths from puerperal infection but the gain is made up by loss of mothers from other causes.

Seven hundred and seventeen deaths were studied as of 1931, 1932 and 1933. Septic abortion heads the list with 22.6 per cent, septicemia showing a percentage of 16.6, eclamptic states 11.9 and hyperemesis 3.3. The figures compared with those issued by the state of Pennsylvania again show that urban mortality rates are nearly double those of the rural districts.

The difficulty in arriving at just conclusions is shown by the joint coding of the causes of death, e.g., in reporting an influenza death during pregnancy, and this point is emphasized in the chapter devoted to comparison with mortality rates in foreign countries. "Until a uniform procedure for preference in joint causes found in maternal deaths is adopted, any comparisons between countries will be useless and futile."

Hospital deliveries showed 72 per cent spontaneous and 28 per cent operative, and the mortality of all the hospitals was 9.1 per thousand.

The incidence of cesarean section in Philadelphia hospitals varied from 0.3 to 11.1 per cent, the largest maternity service showing 4.8 and the average being 2.6 per cent. There were (in the three years) 1,775 cesarean sections, with 98 deaths or 5.52 per cent. Two "lost" cesarean deaths were discovered after the tables were made. The mortality of classic cesarean section was 74.5 per cent of the total ninety-eight deaths and 14.3 per cent for the low cervical, again proving beyond, now beyond justifiable doubt the immense superiority of the low cervical cesarean operation.

The figures show an increase of operative deliveries and at the same time an increase of fetal injuries and deaths of 62 per cent in ten years. In Philadelphia 73.5 per cent of all live births occurred in hospitals.

It was impossible to compare the results of home delivery with those of institutional, and one does not know what significance to attach to the figures. Of ninety-eight septic deaths seventy-seven are accredited to intrahospital infection, and of the seventy-seven patients sixty-six were "planned admission" cases.

A careful analysis of the deaths is made from many angles, and a good discussion of each factor is given, also recommendations for prevention. One might disagree with some of the opinions regarding preventability of these deaths. It is hard to judge what should have been.

This report is a valuable addition to our obstetric statistics and will help all teachers to teach and do better obstetrics, and hospitals to improve their service.

Blothérapie chirurgicale anti-infectieuse. Ses procédés. Vaccins sérum thérapeutique par le choc. Immunisation transfusion leucocythérapié bactériophagothérapie. Ses applications ses limites. Par J. P. Lamare et Maurice Larget, chirurgiens de l'Hôpital de St. Germain en Laye. Paper. Price 30 francs. Pp 264. Paris: Librairie Louis Arnette 1934.

This readable work is divided into two sections. In the first is a concise presentation of most of the well established ideas on vaccines, serum, blood transfusions, therapy of shock, non-specific leukocytic stimulation, and bacteriophage. Particularly helpful are the suggestions and contraindications for the use of serums and vaccines. The second portion of the book deals more with the specific diseases in which one or more of the foregoing therapeutic procedures is indicated. The portion on osteomyelitis and puerperal sepsis is quite extensive, but vaccine therapy in ulcerative colitis is not considered nor is the subject of preoperative preparation dealt with to any extent. It is probable that the authors feel that these two subjects are not sufficiently established to warrant more emphasis. No bibliography is included, although generous and frequent mention is made of other workers in this field. The book appears to be one to which one may turn for the present-day conception of these subjects but with no new or original additions. It is primarily a reference book for the clinician, not the investigator.

Osteomyelitis: Its Pathogenesis, Symptomatology and Treatment. By Abraham O. Wilensky, A.B. M.D. F.A.C.S. Attending Surgeon to the Bronx Hospital and Dispensary, New York. Cloth. Price \$8. Pp 454 with 104 illustrations. New York: Macmillan Company 1934.

The author bases his book on the conception that the pathologic changes which occur in cases of osteomyelitis are of vascular origin and are to a large degree mechanistically determined. He has delved into the field of bacterial infection, neurology, otology, rhinology and the history of medicine. He has taken much from his writings that have appeared in many periodicals and from numerous other sources. The historical development of knowledge concerning osteomyelitis is an interesting chapter. The author likes the Orr treatment but does not like the use of maggots. It is surprising that the work of Starr, a pioneer whose work forms a milestone in the pathogenesis and rational early treatment of osteomyelitis, has been entirely neglected. His name does not even appear in the index. Nor does the name of Platt appear. The work of Dean Lewis appears in four places, which are purely statistical. The excellent work of the Englishman Kennon is entirely neglected. Lincoln, Neb., would resent the statement on page 226, where Orr is credited to Kansas City.

Krankheiten der Leber und der Gallenwege. Eine Darstellung für die Praxis. Von Professor Dr. F. Rosenthal, Fachbücher für Ärzte. Band XVI. Herausgegeben von der Schriftleitung der klinischen Wochenschrift. Cloth. Price 18.80 marks. Pp 216 with 6 illustrations. Berlin: Julius Springer 1934.

This is an excellent little treatise on diseases of the liver and the bile tracts. It is replete with discussions on the newer phases of physiology of the liver and their clinical application as well as with a fairly thorough description of pathologic anatomy, clinical considerations and methods of treatment. The technic of the commoner and more useful laboratory procedures as the tests of liver function, are described in sufficient detail. Discussions of differential diagnosis when necessary, are not lacking. Especially creditable are the sections devoted to the cirrhoses of the liver. Under the caption of diseases of the extrahepatic biliary tract the new subject of biliary dyskinesia and the causes, symptoms and treatment are described quite well. One would wish that more space were given to the acute disorders of the gallbladder and that mention of the effect of obstruction of the common duct on the pancreas were made. The bibliography is meager although many more authors are mentioned in the text without their names appearing in the list. With the exception of the work of Mann and Magath and of Graham and Cole, English and American authors are quoted rather meagerly. However, it is quite an acceptable piece of work of its size.

Medicolegal

Paternity Blood Grouping Tests to Determine Paternity—The plaintiff sued the defendant for damages for a carnal assault, alleged to have been committed by the defendant, as a result of which the plaintiff gave birth to a child. The defendant, denying all of the material allegations of the complaint, requested the court to require the plaintiff and her child to submit to a physical examination pursuant to the provisions of section 306 of the Civil Practice Act of New York, and, in connection therewith, to permit the taking of samples of blood of the plaintiff and her child for examination and analysis. Section 306, Civil Practice Act of New York, provides in part as follows:

In an action to recover damages for personal injuries if the defendant shall present to the court satisfactory evidence that he is ignorant of the nature and extent of the injuries complained of the court by order shall direct that the plaintiff submit to a physical examination by one or more physicians or surgeons to be designated by the court or judge.

The examination sought, said the Supreme Court of New York, Kings County, is clearly relevant to the issue of paternity. The question to be determined is whether the Landsteiner blood grouping test, which is here sought to be applied is generally recognized as sufficiently trustworthy for use as an aid in ascertaining facts in a legal proceeding. If so, the court said, then by general common law principles the proposed examination should be permitted. The law has at all times said the court, even though on occasions haltingly, appreciated the need of keeping abreast of achievements in fields other than its own. It has thus recognized as trustworthy and has made use of, numerous scientific advantages. The Binet Simon Intelligence Test was used during the course of a Connecticut trial *State v. Wade* 96 Conn. 238, 113 A. 458. Experts are permitted to testify that a given specimen of blood is human and evidence of fingerprints is admitted to prove identity. *People v. Roach* 215 N. Y. 592, 109 N. E. 618. With respect to the present case, the court said, research of medical journals and foreign law reports discloses that many thousands of similar cases have been before the courts of European nations. The evidence submitted on the hearing of this case, continued the court and a reference to scientific works cited in support of the application, lead to a conclusion in keeping with that of the Supreme Italian Court of Cassation (*Lattes, Individuality of the Blood*, p. 254), where the following appears:

As regards the reliability of the results obtained by this method the latest studies and investigations show that though the determination of the blood groups affords no positive evidence for a declaration of filiation in a given case it does on the other hand furnish incontrovertible evidence for the exclusion of this relationship when the child's blood group does not agree according to a definite scheme with that of the supposed father.

Naturally, continued the court, the application of scientific tests will not be permitted where such tests have not attained definite and dependable results accepted generally by those qualified to judge. Thus, a federal court has refused to permit the use of the systolic blood pressure deception test because it had not gained sufficient scientific recognition. *Frie v. United States* 54 App. D. C. 46, 293 Fed. 1013, 34 A. L. R. 145. The Landsteiner blood grouping test, on the other hand, has been generally accepted by the medical profession, said the court. The Supreme Court was convinced that the reason and the exigencies in the present case fully justified the granting of the application, subject to such restrictions and directions as the court might deem proper. On appeal, however, to the appellate division of the Supreme Court, second department, the order directing the plaintiff and her child to permit the taking of blood for the purpose of determining the defendant's paternity of the child was reversed. The appellate division of the Supreme Court stated that the plaintiff might submit to the taking of a specimen of her own blood, but it plainly would determine nothing. She admits that she is the mother of the child. A blood test of the defendant and the child might possibly determine the defendant's nonpaternity but it was not claimed, nor

was there any evidence in the record to show, that the test would determine the defendant's paternity. The child was not a party to the action, continued the court, and while the court of chancery has an inherent jurisdiction over the welfare of an infant a ward of the court, nothing in this case indicated in the slightest that the welfare of the child was in any way involved or that the blood test could possibly be beneficial to the child. Section 306 of the Civil Practice Act, concluded the court, had no application to the facts of the case.—*Bruschel v. Manowitz (N. Y.)*, 271 N. Y. S. 277, 272 N. Y. S. 165.

Compensation of Physicians Liability of Corporation for Services Rendered at Agent's Request—Deering, an employee of the Shredded Wheat Sales, Inc., employed the plaintiff-physician to treat a boy injured by one of the corporation's trucks, promising, according to the plaintiff's testimony that the corporation would pay for the services rendered. Deering reported the accident and the name of the attending physician to the corporation and, at its request, reported the boy's progress weekly. Later, Gale, one of the corporation's assistant sales managers, came from Boston to Providence, where the child had been injured, to investigate the case and visited the boy in the hospital. On the corporation's failure to recompense the plaintiff-physician, he brought suit against the corporation and Deering. The trial court, on the motion of the defendants, granted a non suit and the plaintiff appealed to the Supreme Court of Rhode Island.

We note, said the Supreme Court, that the name of the plaintiff appears in the pleadings as "Dr. James Hamilton." The designation "Dr." is a title and is no part of the name of the plaintiff. It is therefore improper pleading so to designate the plaintiff. For the purposes of the motion for a non suit, continued the court, the plaintiff is entitled to every inference of fact favorable to him which can reasonably be drawn from the testimony. In view of the reports made to the corporation and the interest it evinced in the boy's condition, it would be natural to expect that the corporation should make some inquiry to ascertain whose credit had been pledged for the boy's care. When Gale was in Providence investigating the case, he knew that the plaintiff was rendering his services at the request of an employee of the corporation. It would have been unreasonable for the officials of the corporation to assume that the employee expected to pay for the treatment. As the corporation at that time had knowledge that its agent had contracted for the medical care of the child, it should have investigated the matter. If inquiry had been made, the facts would have been learned. The officials of the corporation, by closing their eyes to available information, are charged with the knowledge which it was their duty to ascertain. Had the corporation desired not to be bound the services could and should have been ordered discontinued. Having failed to speak when it should, the corporation may not speak now when it would. The Supreme Court concluded that from the uncontradicted evidence the jury might reasonably have found that the corporation knew, or had reason to believe, that the plaintiff was rendering services and charging them in good faith to the corporation. The case should have been submitted to the jury. The action of the trial court nonsuiting the plaintiff was therefore declared erroneous, and a retrial of the cause was ordered.—*Hamilton v. Shredded Wheat Sales Inc. (R. I.)*, 172 A. 614.

Current Medical Literature

AMERICAN

The Association library lends periodicals to Fellows of the Association and to individual subscribers to THE JOURNAL in continental United States and Canada for a period of three days. Periodicals are available from 1925 to date. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 12 cents if two periodicals are requested). Periodicals published by the American Medical Association are not available for lending but may be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.

Titles marked with an asterisk (*) are abstracted below.

Infection in Man Caused by Yeastlike Organism—

Hausmann and Schenken report the case of a chronic infection produced by a yeastlike organism belonging to the genus *Sepedonium*. The infectious agent was apparently localized in the skin and the regional lymph nodes for a period of about fifteen years. The skin was thickened and scaly throughout the course of the disease except during the last three months of life when the characteristic papular lesions developed. It is possible that this fungous infection could have been a secondary infection engrafted on a nonspecific scaly dermatitis but the presence of the yeastlike organism in the skin and lymph nodes for at least a year and a half before the lesions became papular and the fact that the enlargement of the lymph nodes

was an early observation make this possibility seem quite improbable. It is the authors' opinion that the disease was initiated by the fungus. The appearance of the organism in tissue, the large spiculated chlamydospores on artificial culture medium and the animal pathogenicity of the organism are the characteristic features by which subsequent cases may be recognized. The infecting organism is similar in the chronicity of the infection it produced, the macroscopic appearance of its growth on artificial culture medium and the formation of spores on lateral branches to the so-called oidium mentioned in medical literature. However, the large spiculated spores, the delicate mycelium and the animal pathogenicity are distinctly different from *Oidium Gilchristi*. Although the authors appreciate that the taxonomy of this large group of imperfect fungi to which this organism belongs, is artificial and often unsatisfactory, it would appear that this organism could not be classified more satisfactorily for the present than with the genus *Sepedonium* since no spore formation from the copulation of hyphae was observed.

Syphilitic Aneurysm of Coronary Artery with Aneurysm of Sinus of Valsalva—In addition to the recognized causes of aneurysm of the coronary arteries such as mycotic-embolic infection and arteriosclerosis, Snyder and Hunter offer another, syphilitic arteritis. They know the accepted belief is that the coronary arteries are rarely affected by syphilis distal to their intra-aortic segments. However, in one of their two cases there is a condition which modifies the usual circumstances, so that they do not hesitate to term the coronary lesion syphilitic. Undoubtedly the involvement of the left coronary artery was dependent first on the localization of an active syphilitic aortitis in the left posterior sinus of Valsalva and secondly on the direction of burrowing of the enlarging sac, which finally brought it into intimate contact with the main left coronary artery. There must then have been a spread of *Spirochaeta pallida* from the wall of the Valsalva sac to the wall of the coronary artery with resultant destruction fusion of the walls of the two juxtaposed structures and, finally, the formation of a true aneurysm in the weakened coronary artery. As evidence of the syphilitic nature of the lesion the authors submit the microscopic observation of obliterative endarteritis of the vasa vasorum perivascular collars of plasma cells and lymphocytes, microscopic gummas, destruction and scarring of the media and adventitial fibrosis. A careful study of the aorta, coronary arteries and myocardium failed to disclose anything that could be interpreted as rheumatic disease. The vascular changes in the coronary artery of this case were quite different from the commonly observed adventitial cellular infiltration accompanying coronary arteriosclerosis. In addition to aneurysm of the coronary artery there was recent thrombotic occlusion of the sacculum and the lumen of the vessel adjacent to it. Death evidently supervened shortly after the thrombus formed for only the earliest indications of infarction of the myocardium were present. In the other case it is possible that the incipient heart block, not evident clinically but suggested by the prolonged atrioventricular conduction time and the inverted T waves of the electrocardiogram may have been caused by digitalis but the authors feel that the Valsalva aneurysm together with degenerative and fibrotic changes in the adjacent myocardium afford a more plausible explanation for these phenomena. Another factor contributing to cardiac failure was aortic insufficiency. The right cardiac hypertrophy probably was due to increased pressure in the lesser circulation bed due both to the stenosis of the pulmonary valve region by the Valsalva sinus aneurysm and also to pulmonary atherosclerosis which in turn probably followed increased circulation pressure from left heart failure on the basis of aortic insufficiency and stenosis of the mitral area from the Valsalva aneurysm. The presence of plasma cells and lymphocytes in the walls of the pulmonary arteries suggests that the sclerosis of these vessels may in part at least have been the result of syphilis. The lesions in the bases of the lungs exhibited the characteristics of gummas and bore scarcely any resemblance to tubercles. Although the spirochete stains failed to demonstrate the organism the authors believe from the microscopic appearance of the lesions and the known syphilitic nature of the aortic disease, that the pulmonary foci are syphilitic as well. The aortic involvement was much more extensive than is usual in syphilis,

and a second saccular aneurysm has developed in the abdominal division of the vessel

Focal Fat Infiltration in Liver—Simon submits a case of localized fat infiltration of the liver resembling lipoma in the gross and not identical with any similar lesion reported in the literature. It is possible that other cases thought to be lipoma of the liver are of the same nature. The lesion does not correspond to the usual picture of lipoma in that there is no trace of capsule and the supporting tissue is made up in considerable part of remnants of the capsule of Glisson. There are no features indicative of malignant neoplasm. That the condition is a localized fat infiltration is supported by the fact that peribiliary structures including bile ducts are found within the mass. There is no positive indication of marginal compression and between the normal liver cells and the fatty mass there is a zone, interpreted as transitional, in which many liver cells show small fat droplets. The process differs from ordinary fat infiltration of the liver in that all the cells within the mass show almost complete distention of cytoplasm by a single, large fat globule.

Voluntarily Induced Increases in Rates of Involuntary Physiologic Processes—Carpenter and his associates determined the total respiratory exchange, pulse and respiration rates, and systolic and diastolic blood pressures in a person in the typical basal postabsorptive condition and in periods of five and ten minutes during which he voluntarily produced an increase in all the factors without apparent visible effort. The increases produced were from 13 to 32 per cent in the oxygen absorption, from 17 to 26 per cent in the pulse rate, from 9 to 28 per cent in the systolic pressure and from 4 to 27 per cent in the diastolic pressure. These changes were devoid of alterations of affect. Only when the subject lay practically nude was it possible to detect any indication of effort on his part. Under the ordinary condition of measurement of basal metabolism the

causes for the increased values would have remained obscure. The observations demonstrate that it is possible for a person to maintain himself in a condition that is not basal but which under the ordinary rules of measurement would be considered conforming to the usual conditions of basal metabolism measurements. The metabolic rate measured under the usual prescribed basal conditions is therefore not necessarily the basal rate.

Acute Pancreatic Necrosis—Parry and Murray discuss twenty cases of acute pancreatic necrosis. The exciting agent is unknown, as is also the route it employs. Infected bile or duodenal contents injected under pressure into the pancreatic duct of an experimental animal causes an acute necrosis of the pancreas closely resembling that seen in man. As yet no satisfactory explanation has been offered in the cases in which the common bile duct and pancreatic duct enter the duodenum separately. Patients suffering from biliary colic who are not rendered relatively free from pain by the hypodermic administration of one-fourth gram (0.015 Gm.) of morphine, repeated in from two to four hours, are probably suffering from some complication of gallstone colic, and acute pancreatic necrosis is an important complication. Although acute pancreatic necrosis carries a higher mortality (40 per cent in the authors' series), there is reason to believe that it is probably not so high as has been heretofore supposed, because undoubtedly many patients who survive do not come to operation. Often the diagnosis may be made before operation if the triad of symptoms and signs is kept in mind, viz. (1) the patient's general condition more acute than is usually seen in biliary colic, (2) pain and tenderness localizing to the left of the midline just above the umbilicus and (3) palpation of an indefinite thickening in the epigastrium (often it is not palpable until the patient is relaxed under the anesthetic). As a prophylactic measure, the removal of infected gallbladders would prevent many of these cases. When a diagnosis of acute pancreatic necrosis is made, immediate surgical attack on the pancreas is not required.

Sedimentation Rate in Rheumatic Infection and the Albumin-Globulin Ratio—Struthers and Bacal observed that alterations in the sedimentation rate which have been shown to occur associated with rheumatic infection in childhood are associated with definite alterations in the albumin globulin ratio. With a rise of the sedimentation rate there is a drop in the concentration of albumin and a rise in the concentration of globulin, and vice versa. The method that they used for the estimation of the albumin-globulin ratios is a combination of the Howes-Kjeldahl and Van Slyke methods. From their

present knowledge it would appear that alterations in the sedimentation rate are dependent on surface tension of the blood and corpuscle volume, hemoglobin concentration and hydremia

Twenty-Four Hour Blood Sugar Curve in Diabetic Patients—Sprague and Newson determined the blood sugar curve in a diabetic patient, aged 12, over a period of twenty-four hours. Blood was taken at intervals of three hours. During this time insulin was administered once, at 4 30 p m., and the patient was given his usual diet of 1,500 calories, each meal of which had a dextrose value of 50 Gm. The blood dextrose determinations were carried out as described by the Schaffer-Hartman method. When these results were plotted, some of the phenomena the authors had been at a loss to understand in adjusting the insulin dosage were indicated. For the first six hours the results corresponded with what would be expected, in that there was slight postprandial hyperglycemia, which gradually subsided. At this point, because of a misunderstanding, 15 units of insulin was administered. There was a marked fall in the blood sugar level which continued on down and reached its lowest point about 11 p m. From this time on there was a marked increase, reaching a peak of 0.237 per cent at 5 a m. This increase took place in spite of the fact that no nourishment was taken after 5 p m. the preceding evening. That this was apparently not an unusual condition was indicated by the fact that the parents found the patient in a comatose state on several occasions late at night and that it was almost impossible to obtain a morning specimen of urine which was sugar free. It was also recalled that all of the patient's episodes of insulin shock had occurred late in the evening. It occurred to the authors that it might be possible to control the glycosuria better by giving the morning insulin at 4 30 a m. before the blood sugar had reached its peak. When this was done it was found that the morning specimen of urine was sugar free, and coincident with this the patient felt better. This study led the authors to carry out similar curves on other diabetic patients.

Postoperative Activity of Leukocytes—Boyd performed a differential lipid analysis of the white blood cells on ten patients before they underwent surgical operation and at intervals of from three to seven days afterward. In one group of seven cases the postoperative course was normal and in the second group of three cases the postoperative course was prolonged, owing to serious complications. One death occurred. The changes in the lipid content of the white blood cells varied according to whether recovery from operation was normal or complicated. In those patients who returned to normal health in the usual time, the striking changes in the blood leukocytes were a rise in the level of phospholipid and free cholesterol (in certain cases an increase of more than 200 per cent was recorded for these lipids). In such leukocytes the values for neutral fat and cholesterol ester were usually low. On the other hand, when the patient did not respond normally to operation and marked postoperative complications developed, the changes in the leukocytes were the exact opposite of this, phospholipid and free cholesterol fell to a third or a half of their value before operation, and neutral fat and cholesterol ester tended to increase in amount. The group of variations in lipids for the former cases corresponds to those characterizing increased tissue activity, those in the latter group, decreased tissue activity. It is therefore possible to follow changes in the activity of the blood leukocytes by measuring their lipid content. The most significant variations occur in phospholipid and free cholesterol. Routine analyses may be restricted to one or both of these. The test may be performed in about three hours. Its use as an aid to prognosis, diagnosis and treatment is discussed and illustrative cases are cited.

Hypothyroidism Induced by Removal of Normal Thyroid in Heart Disease—Blumgart and Davis outline the development characteristics and control of the hypothyroid state induced by total ablation of the normal thyroid, with especial reference to the signs and symptoms of hypothyroidism, the basal metabolic rate and the serum cholesterol. They describe a method of thyroid medication whereby the hypothyroid level, after total thyroidectomy, may be controlled so that patients with heart disease may be free from the distressing symptoms of myxedema and yet gain the benefits afforded by reduction in the work of the heart. In addition to the foregoing manifestations of hypothyroidism, which are present at a basal metabolic level of from minus 25 to 30 per cent, the authors have also observed the development of a mild anemia and a lowering in the free hydrochloric acid in the gastric secretion. No clinical symptoms have been associated with these changes. At this controlled level of metabolism they have also noted changes in electrocardiographic tracings and heart size characteristic of mild hypothyroidism. These changes were not accompanied by a decreased functional myocardial capacity, on the contrary, these patients with chronic heart disease have shown improvement in the face of such changes. Kidney function and carbohydrate tolerance are not diminished in these patients. In brief, hypothyroidism can be induced by total ablation of the normal thyroid, and the level of the hypothyroid state thus induced may be controlled, so that the patients remain comfortable and yet gain the benefits afforded by reduction in cardiac work. Under these conditions of reduced metabolism, the relief that has been afforded many patients with chronic heart disease has been definite. The symptoms that characterize the level of hypothyroidism maintained in these patients after operation are slight and, in the patients' opinion, insignificant in comparison with the benefits derived.

Demonstrating Estrogenic Substance in Blood—Fluhmann describes the technique of a biologic test for the demonstration of estrogenic substance in the blood. The test depends on the injection of small amounts of untreated serum into spayed mice. A positive result is indicated by the production of a "mucification" of the vaginal mucosa. The method may be applied to quantitative studies, provided a sufficient number of test animals are employed. The examination of eighty specimens of blood obtained from forty-six women at different stages of the menstrual cycle shows that in this series the maximal concentration of estrogenic substance was reached during the middle of the interval, a secondary rise occurred at the time of the flow, and it was diminished just before and just after menstruation.

The Hypophysis Cerebri and Pregnancies—Stein studied a group of ten virgin white rats in comparison with a group of ten litter mate test animals, which had had three pregnancies in rapid succession. The average body weight of the test animals was 38 Gm. heavier than the controls, which proves to be a significant difference; however, the body length of the test animals was not significantly greater than that of the controls, being only 0.8 cm. The average weight of the whole hypophysis in the test group was not significantly greater than that of the control. Evidence is submitted that utilizing every tenth section cut at 5 microns was sufficient to determine the relative size of the various lobes in the rat's hypophysis by the paper weight method. The posterior lobe of the test animals was proved to be increased over that of the controls, but the anterior and intermediate lobes showed no significant differences. A differen-

tial count of the cells in the anterior lobe (based on counting about 9,000 cells in each hypophysis) showed no significant difference between tests and controls. The average percentages for the test animals were 70.5 per cent chromophobes, 25.8 per cent acidophils and 3.7 per cent basophils, for the control group the corresponding figures were 72.9, 23.6 and 3.5. The cells in the two groups were apparently equal in size, for the 'average number of cells per field' were practically equal in number for the test and control groups. From the standpoint of number, size, shape, nuclear pattern, staining reaction or distribution of cells in the gland, no definite or unique histologic feature could be found in the hypophysis of the pregnant group. No special cell that could be designated 'pregnancy cell' as described by others for the rat was evident.

Study of Persistent Pyuria—Summerfeldt and Brown present results of the study of forty cases of persistent pyuria. The investigation included clinical, intravenous pyelography and cystoscopic examination. From a clinical point of view a complete urologic investigation is indicated in any case of pyelitis in which the urine shows pus over a period of four weeks. The investigation has shown that the great majority of cases of chronic pyuria are due to inadequate drainage due to an obstruction of the urinary tract. The treatment has been directed to relief of the obstruction present. The immediate results are fairly satisfactory, but the end results as far as kidney infection is concerned are indefinite. In these treated cases though there may be recurrence of pus in the urine, there is noted a definite improvement in the general health of the patients.

Gangrene of Extremity in New-Born—Dohan reports a case of gangrene of the left lower leg and foot, which appeared about the thirteenth postnatal day. Serologic tests of the blood

for syphilis were negative on the parents. The infant's serologic tests of the blood for syphilis were negative on repetition, following a moderately positive reaction in the first blood sample. A roentgenographic examination of the legs was negative for bony displacement but indicative of congenital syphilis. Histamine tests showed a circulatory efficiency of the non-gangrenous leg that was distinctly below normal. Blood sugar, blood coagulation, blood counts and urinalysis, as well as body temperature and other clinical observations, deviated so slightly from the normal that they were not considered positive evidence. Pathologic and bacteriologic studies were inconclusive. Trauma, infected or noninfected embolism, constricting amniotic bands and angiospasm may all play a part.

Idiosyncrasy to Ammoniated Mercury Ointment—Harper states that local application of ammoniated mercury in two cases gave a generalized rash and stomatitis together with a peculiar cyanosis and edema of the hands and feet. It is believed that the symptoms were manifestations of an idiosyncrasy to mercury rather than the results of absorption of relatively large amounts. Presumptive evidence for this is found in the rapid development of symptoms after application of relatively small amounts of ammoniated mercury, in the experimental demonstration that the absorption of mercury in this form is relatively poor, in the rapid recovery following the withdrawal of the drug in the absence of evidence of renal damage and finally in the acute and severe reactions to skin tests.

Sudden Exanthem with Encephalitic Onset—Wallfield reports an uncommon case of sudden exanthem, which was ushered in by symptoms simulating encephalitis in a boy 12 years of age. After a high fever of three days, a critical drop in temperature occurred, followed by a rash typical of sudden exanthem in its morphology, distribution and duration with a rapid and uncomplicated recovery. The blood picture showed the characteristic leukopenia.

Abortive Treatment of Volkmann's Ischemia—Pusitz reports a case of early Volkmann's ischemia in which the following operation was performed. Under general anesthesia, long incisions were made through the skin, subcutaneous tissues and the deep fascia of the forearm (the so-called vaginal fascia of Prentiss). When the deep fascia was cut, the muscle mass bulged right out of the opening. A great deal of blood escaped from these cuts. With Mayo curved scissors, the muscle bundles were separated slightly by blunt dissection. Petrolatum gauze and then dry dressings were applied over the wounds. Almost immediately after the patient had recovered from the anesthetic he stated that he felt some relief. About five hours later the fingers could be moved slightly. They were still somewhat numb but the blueness had been replaced by a pinkish coloration. The fingers were not cold. The progress of the patient was a very slow, gradual improvement so that two weeks after operation practically all the swelling had cleared up. The motion of the fingers had improved greatly, although still far from normal. The stitches were removed and a nonpadded cast was applied according to the method of Böhler. The patient was discharged from the hospital and seen periodically in the office. Callus was very slow in appearing and it wasn't until five months later that the cast was removed. At that time it was noted the patient moved his fingers fairly well, there was good flexion and extension of the wrist but there was no pronation and supination. He was therefore told that he had a possible synostosis between the radius and ulna and advised to have an operation. For the time being he was placed on physical therapy. Two months later he stated that his motion with reference to pronation and supination was increasing and that he was not going to return for further operative work.

Posttonsillitic Pyemia—Myers reports three cases of pyemia following acute infection of the tonsils. The first case is that of a white man, aged 22, whose illness began with an acute tonsillitis followed by peritonsillar abscess. The subsequent course was that of generalized sepsis. The site of a thrombophlebitis was not determined. There were septic metastases to the lungs, pleurae, pericardium, wall of the chest, right buttock and right ankle. An anaerobic streptococcus was grown from the pus several times from different locations. The patient died forty days after the onset of sore throat. In the second case thrombosis of the left internal jugular vein developed subsequent to acute tonsillitis in a youth, aged 16. There were metastatic septic lesions in the lungs and pleurae and signs of venous stasis in the basal cerebral ganglions. Streptococcus haemolyticus was recovered from the pleural fluid. The course led to death three and one-half weeks after the onset of the sore throat. The third case is that of a man, aged 36, who developed a left peritonsillar abscess in the wake of an attack of acute tonsillitis. The course of the illness was one of sepsis with an abscess of the right buttock and urinary signs of involvement of the kidney. Streptococcus viridans was recovered from the blood. The patient died six weeks after the onset of the sore throat.

Caprokol as an Anthelmintic—Tubangui and his associates investigated the efficiency of caprokol in 861 persons harboring different types of human intestinal worms. The drug was given in hard gelatin capsules and in the form of sugar coated pills, in the doses recommended by the manufacturers. It was administered early in the morning on an empty stomach and the patients were advised not to take food for at least four hours afterward. Each patient received only one treatment. Caprokol was found to suffer in anthelmintic efficiency when placed in gelatin capsules, owing most probably to the reaction of the drug with the gelatin. The capsules themselves underwent rapid deterioration if they remained intact, they were easily broken in the mouth during the process of swallowing. The sugar coated pills, besides being more efficacious than the gelatin capsules, did not appear to be affected by climatic conditions. Their anthelmintic efficiency was appreciably increased by a saline purge twenty-four hours after their administration. In infestations with ascaris and hookworms the administration of single doses of caprokol pills removed from 82 to 85 per cent of the former parasite and 74 per cent

of the latter. Of the ascaris cases from 53 to 64 per cent were found negative after the treatment and of the hookworm cases 25.4 per cent. In trichurias infestations, caprokol was found to be apparently effective, but some doubt is expressed as to the accuracy of judging the efficiency of the drug from the results of differential egg counts before and after treatment. Observations in a limited number of cases showed that caprokol is effective also against the human pinworm (*Enterobius vermicularis*) but not against the tapeworm (*Taenia saginata*).

Méniere's Disease Complicated by Interstitial Keratitis—Mogan and Baumgartner obtained a striking result following the removal of both superior ganglions in a case of Meniere's disease with recurrent interstitial keratitis. They believe that this offers a plausible theory as to the etiology of Meniere's syndrome, as well as a suggestion for further study in the treatment of this and associated conditions. In their case the peculiar periodicity, the unilateral sweating of the body and the whiteness of the bulbar conjunctiva preceding marked hyperemia, all pointed to some altered physiology of the sympathetic nervous system, somewhat resembling Raynaud's disease. They believe that the result obtained from the removal of the superior cervical ganglions and trunks is conclusive. They feel that a disturbance of the sympathetic nervous system must be considered an etiologic factor in Meniere disease. Otosclerosis is probably due to a metabolic disturbance in the petrous portion of the temporal bone, and the authors believe that it is not illogical to assume that it likewise might be due to altered function of the sympathetic nervous system. Results will of course not be satisfactory after permanent damage has resulted, and if ganglionectomy is attempted at all it must be done early.

Reticulo-Endothelial Cells in Combating Infections—Tashian states that local immunity or the defense mechanism of the skin, has been demonstrated by experiments on animals and clinically verified. The histiocytic or reticulo-endothelial system has been shown to be by far the most important factor in local tissue resistance against infection. The absence of histiocytes indicates a lowered tissue resistance and a fertile soil for bacterial intrusion and growth. A superior nonspecific active immunity may be acquired by nutrient broth injections. The author describes a varied number of cases for guidance as to the possible use of nutrient broth. Experience with indolent cutaneous ulcers should precede its employment in other conditions. He compounds a preparation that he believes is superior to the so-called laboratory nutrient broth. In more than 1,500 injections he has had only two cases that showed a mild degree of hypersensitivity. Neither case necessitated injection of epinephrine. He presents this only as an adjunct to already established procedures to combat infections.

Epileptic Convulsions—Denny Brown and Robertson present an account of the cerebrospinal fluid pressure respiration and muscular movement in six epileptic patients. They observed that during epileptic convulsions the pressure of the cerebrospinal fluid shows changes reflecting passively the fluctuations of venous pressure arising chiefly from involvement of the thorax in the convulsion. The cerebrospinal fluid pressure rises in sleep and there is fluctuation in drowsy states. A slow fall of pressure preceding a convulsion is evidence only of an awakening of the patient. Certain phenomena such as awakening starts or even local spinal reflexes may enhance the tendency to epilepsy and thus appear to be the direct excitant of discharge. Such effects when they occur are examples only of the addition of one nervous excitation to another. The convulsive stage of the epileptic attack is essentially an incoordinated discord resulting from the diffuse excitation of outgoing cortical neurons. Even in the most localized forms of epilepsy the essential epileptic process does not appear to be directly located in these neurons. The exhaustion of nervous activity underlying postepileptic hemiplegia is related to threshold changes in the excitability of pyramidal neurons, whereas the intervals between attacks and the fluctuations in tendency to attacks are related to an unphysiologic mechanism which has no defined anatomic place.

Congenital Syphilis in Mentally Defective Adults—Paddle states that of 1,598 adult mentally defective patients of all grades and both sexes, in whom the Wassermann and the Memcke macroclarification tests were done on the blood serum, the cerebrospinal fluid of 1,525 was examined by the Wassermann test. Pandey's test, Lange's colloidal gold test and for increase of cells. Of these, 106 gave various abnormal reactions in the blood or cerebrospinal fluid and 1,492 were serologically negative. Of the 106, seventy-five were considered to have congenital syphilis and of the 1,492 serologically negative cases three were deemed on clinical and other grounds to be congenitally syphilitic, giving a total of seventy-eight cases of hereditary syphilis or an incidence of 4.9 per cent. The Memcke clarification test of the blood serum in adults was more sensitive than the Wassermann test. The incidence of congenital syphilis was higher among imbeciles than among idiots or the feeble-minded and higher in crippled epileptic patients than in uncomplicated cases. There was no evidence to show that mongolism was caused by syphilis. Conditions such as cretinism, choreo-athetosis and postencephalitic lethargy were unconnected with congenital syphilis. Of the 1,525 cases, excluding ten cases of acquired syphilis with four abnormal fluids, the cerebrospinal fluid was abnormal in thirty, or 2 per cent. In seventy-six cases of congenital syphilis the fluid was abnormal in sixteen, or 21 per cent. The incidence of congenital syphilis was found to fall with advancing age but it differed in the sexes. In females it was highest in children and lowest between the ages of 31 and 40 years with a sharp rise between 41 and 50 suggest-

ing a menopausal influence on the serologic tests used. At this age the incidence among the males was at its lowest, but there was a subsequent rise.

Unusual Type of Cortical Gliosis—Stewart discusses the case of a feeble-minded man with Erbs' juvenile type of muscular dystrophy who died after the disease had been in existence for twenty years. During life the patient exhibited a bilateral and symmetrical enlargement of the salivary glands. The terminal illness was ushered in by a marked and persistent hypothermia, bradycardia, low blood pressure, profuse salivation, repeated vomiting, miosis and a positive oculocardiac reflex. A sudden failure of the autonomic nervous system may have caused these unusual terminal symptoms. Pathologic examination confirmed the diagnosis of muscular dystrophy, and, in addition, revealed the presence in both cerebral hemispheres of a special type of glial hyperplasia, this took the form of small, raised wartlike nodules in the cortical gray matter, numerous in the frontal convolutions and diminishing in number toward the occipital poles in many situations accompanied by a disturbance of cytoarchitecture and by the presence of primitive nerve cells. No glial or neurotic cells of giant type were found and the visceral organs contained no tumors. The condition appeared to represent an unusual type of primary gliosis rather than an abortive form of tuberous sclerosis.

Effect of Hematopoietic Factor of Yeast in Pernicious Anemia—To avoid contact with traces of intrinsic factor possibly present in the gastric juice of cases of Addisonian pernicious anemia Ungley and James administered by other routes yeast products that influenced blood regeneration when given orally. The negative results of parenteral therapy under such conditions supported the hypothesis that the hematopoietic effect of yeast was due not to a substance resembling the liver active principle but to the extrinsic factor of Castle. The factor was present in the 65 per cent alcohol soluble fraction of fresh (nonautolysed) brewers' yeast. Autolysis did not increase noticeably the potency of yeast for blood regeneration in pernicious anemia. There was no parallelism between the vitamin B₁₂ potency of yeast extracts as tested in rats and their effect on hematopoiesis in pernicious anemia. Including the previous series, eighteen patients with Addisonian pernicious anemia have received yeast or wheat germ by mouth, and ten of them have shown some hematopoietic response. Many cases of pernicious anemia, although associated with a histamine refractory achylia, may retain the ability to secrete the intrinsic factor and a hematopoietic response to yeast is an indication of this functional activity on the part of the stomach. There was no correlation between the secretion of the intrinsic factor, as indicated by the hematopoietic response to yeast and the secretion of acid pepsin or chlorides, as determined by gastric analysis after histamine stimulation. In those cases of megalocytic hyperchromic anemia in which the response to yeast is marked, it is probable that causes other than the deficient secretion of the intrinsic factor have contributed to the development of the syndrome. The value of the observations on the hematopoietic effect of yeast in elucidating the etiology of such anemias is discussed.

Oxycephaly—During the last three years Skipper has had under observation a mother and two children suffering from oxycephaly who exhibited certain unusual features. One of them was subjected to cranial decompression. The cardinal symptoms of oxycephaly are defective vision and headache. The former is almost invariable, and is most commonly noticed during the first five years of life. It varies from slight impairment to complete blindness and is due to optic atrophy following papilledema. Papilledema has usually given place to atrophy before the patient is brought for medical examination. Atrophy

progresses to a certain extent in childhood and then remains stationary, never leading to blindness in adult life. It may result from increased intracranial pressure. Evidence of high intracranial pressure in oxycephaly is seen in the convolitional atrophy of the skull bones and in the bulging of the brain when the dura is incised at operation. In one case the intraventricular pressure was measured directly and it was much above normal. The suggestion that atrophy is caused by constriction of the nerve within the optic foramen has not been confirmed generally. Possible contributory causes may be stretching of the optic nerves from upward displacement of the brain during the vertical expansion of the skull and stasis in the retinal vessels consequent on defective return of venous blood from the head. Greig has shown that the jugular foramina may be small and the circulation in the jugular veins negligible. Intelligence is generally normal but may be impaired, poor vision undoubtedly contributing to this in many instances. The oxycephalic patient is usually a mouth breather from deflection of the nasal septum and deformity of the posterior nares. Anosmia is frequent. Uncommon symptoms are convulsions, deafness and loss of the sense of taste. The author's patients had an extremely mild degree of cranial deformity and he has found no record of any instances of oxycephaly in which the departure from the normal configuration of the skull was so slight. Usually the oxycephalic head is too high, short and broad, the first characteristic being the most striking. In his cases, which are evidently examples of delayed oxycephaly, the general shape of the head is almost normal, and only one patient is brachycephalic. Yet the cases are in all other respects typical examples of oxycephaly, and the diagnosis cannot be doubted. The crested vertex, deflected nasal septum, palatal deformity and the condition of the eyes of each patient are particularly characteristic. Roentgenograms of the skull revealing convolitional atrophy and no trace of sutures are, in conjunction with the clinical signs, diagnostic. The chief object of treatment is the prevention or the arrest of damage to vision.

Plasma Proteins and Cardiac Edema.—Thomson presents the results of an investigation of the plasma proteins in fifty-four cases, consisting of eighteen cases of heart failure with edema, sixteen of heart disease accompanied by edema, six of chronic interstitial nephritis, four of tuberculosis, a miscellaneous group of seven cases, and three junior members of the hospital staff who were used as normals. He observed a distinct diminution in the plasma proteins in cardiac edema, 87.5 per cent of the cases showing a plasma albumin content of less than 3.2 Gm per hundred cubic centimeters. In heart disease without edema there is only a slight diminution in the plasma proteins as compared with the normal, 87 per cent of the cases showing a plasma albumin level greater than 3.2 Gm per hundred cubic centimeters. In view of these observations the author suggests that plasma protein deficiency plays an important part in the etiology of cardiac edema. The main cause for the plasma protein depletion in cardiac edema is considered to be malnutrition. He also suggests that the dietary of patients with cardiac edema should contain the maximal amount of protein compatible with their digestive powers.

Hyperparathyroidism and Angiospastic Syndromes.—Bastai and Dogliotti report five cases of partial parathyroidectomy for endarteritis obliterans (Buerger's disease). The following results occurred: (1) lowering of blood calcium more or less and approaching normal values, (2) immediate cessation of pains even when intense and of long duration, (3) subjective and objective increase in the local temperature of the affected parts and increased sweating, (4) rapid healing of wounds that had resisted all types of earlier treatment, and (5) in cases in which hypertension existed, a lowering of the arterial pressure. They believe that in a normal person the calcium-phosphorus ratio and the other elements of similar action are in perfect relationship. Thus the vasomotor action may be regulated according to the functional requirements of the organs by the simple supply of sufficient blood. In disease, however, an excess of calcium ions may cause an increase in contractility and of the angiospastic state with all its consequences. It is in correcting this factor that parathyroidectomy exerts a favorable action on endarteritis.

- *Ovarian Treatment in Hemophilia. E. Schiavo—p 1881
- *Comolli's Distinct Sign in Fracture of Scapula. G. B. Cengiarotti—p 1890

Treatment of a Case of Hemophilia.—Schiavo says that the oral administration of recently prepared ovarian extract, given in small doses and for a prolonged period, is valuable in the prevention and treatment of hemophilia. In his patient aged 11, amputation of a phalanx of the finger was necessary owing to osteomyelitis. The subsequent hemorrhages endangered the life of the child. The operative wound failed to heal. Oral administration of freshly prepared ovarian extract, as mentioned, checked the hemorrhage and favored the healing process of the operative wound up to recovery.

Comolli's Sign in Fractures of Scapula.—Comolli's sign for the diagnosis of fractures of the scapula, more particularly of the surgical neck and body of the scapula, was described in the *Zentralblatt für Chirurgie* 59:937 (April 9) 1932 (abstr. THE JOURNAL, July 2, 1932, p 91). The sign is a typical swelling that develops in the region of the involved scapula shortly after the trauma. The triangular swelling is due to the fact that blood from the fracture gathers in front as well as in back of the scapula. As a result of the peculiar anatomic conditions the blood cannot escape and a cushion-like swelling corresponding to the outline of the scapula, appears. Cengiarotti reports a case of fracture of this type in which the sign appeared with clear characteristics and lasted about eight days.

Anemia and Angina Pectoris.—The assumption that anemia may be the cause of angina pectoris induced Hochrein and Matthes to study the circulation of animals particularly the

blood perfusion of the heart, during anemia and to investigate in a larger clinical material the subjective and objective signs of coronary insufficiency. They found that in the anemia of venesection (loss of blood up to 8 per cent of the total quantity) the withdrawal of the blood is compensated for by evacuation of the blood depot so that there is no reduction in the circulating blood. The arterial pressure, the pulse and the blood perfusion of the heart remain as a rule unchanged. If greater amounts of blood are withdrawn the arterial pressure and the circulation become reduced. The blood perfusion of the heart generally remains constant for longer periods, occasionally it increases or decreases together with the systemic circulation. These observations indicate that the anemia of venesection produces, as far as the heart action is concerned, no impairment but rather an improvement of the coronary circulation. Observations on patients with pernicious anemia, secondary anemia and angina pectoris indicate that the relations between anemia and angina pectoris are extremely slight. Among 297 patients with angina pectoris, the authors observed only five patients with anemia (1.7 per cent), and three of these had an organic coronary disturbance. It may be assumed that patients with anemia because they tire easily, are little exposed to the danger of overtaxing the heart. The assumption of coronary insufficiency is based on electrocardiographic signs (deep Q, abnormal ST) that are not at all typical. The authors observed patients with severe anemia who had neither subjective cardiac symptoms nor electrocardiographic changes.

Cerebral Disturbances of Sodium Chloride Metabolism

—After describing experiments on animals, Molnar and Gruber report sodium chloride tolerance tests on patients. Correct conclusions may be drawn only if the standard diet is known and after a prolonged period of observation. Disturbances in the sodium chloride metabolism, which are due to a changed nervous regulation, only rarely lead to clinical manifestations. Latent disturbances without clinical manifestations but demonstrable with the tolerance test are comparatively frequent. Of eleven patients with cerebral lesions, only one (with acromegaly and diabetes mellitus) had a normal sodium chloride metabolism. The sodium chloride metabolism may appear normal when the reduced concentration capacity of the organism for the chloride ions is compensated by a polyuria. Sodium chloride retention is due either to a weakness of the organism in the concentration of the chloride ions to an absolute or relative oliguria, or to the simultaneous appearance of these disturbances. In three of eleven cases the sodium chloride content of the blood stood at 620 mg per hundred cubic centimeters that is at the upper limit of normality already before the tolerance test, while in two others it even reached 632 mg per hundred cubic centimeters. In some patients the salt retention was dry, that is, there was no increase in weight during retention and the increased elimination was not followed by a loss of weight. A portion of the retained sodium chloride is found in the blood, but the largest part is stored in the tissues. The existence of a disturbance in the sodium chloride metabolism does not permit a localization of the lesion, for such disturbances have been observed in apparently isolated disorders of the hypophysis as well as of the striatum.

*Does Roentgen Irradiation Effect Considerable Improvement in Mongolian Idiocy? W. Lange and H. Hippe—p. 306

Roentgen Irradiation and Mongolian Idiocy.—Lange and Hippe employed von Wieser's method of roentgen treatment in nine children with mongoloid idiocy. Because all of them were older children, their ages varying between 7 and 13, the authors decided to irradiate the base of the skull from five fields: the forehead, vertex, occiput and both temples. The fields were 6 by 8 cm in size, the distance was 30 cm, the filter consisted of 0.5 mm of copper and 1 mm of aluminum, the tension was 160 kilovolts and the current strength was 6 milliamperes. Depending on the character of the case, from 5 to 15 per cent of the unit skin dose was applied to each field.

The irradiation of the different fields was done at intervals of seven days, and pauses of from three to six weeks were interposed between the series. The treatment was continued on the average for about two and one-half years. The irradiations were not followed by unpleasant complications. Since two of the children left the institution before the completion of the treatment, only seven could be observed to the end and could be subjected to after-examinations. An improvement in the mental alertness was observed in only one of the cases. Superficiality and giddiness improved in one girl. The concentration capacity remained unchanged in all the children, even in one of the boys in whom the intelligence quotient had increased greatly. In all, the results of the treatment were so insignificant that no particular value can be ascribed to it. Not a single child was improved to the extent that it might later become capable of earning a livelihood.

"Blood Group Ferment" in Saliva.—Sievers, after calling attention to studies by Wittebsky and particularly to those by Satoh reported in the *Klinische Wochenschrift* (13 798 [June 2] 1934, abstr. THE JOURNAL, July 28, 1934, p. 1690), describes his own studies on this subject, which have direct connection with those of Satoh in that they aimed at determining whether the amount of blood group ferment in the saliva undergoes in the course of the day certain fluctuations dependent on the meals, and whether these fluctuations are independent of the other constituents of saliva. The author was able to corroborate Satoh's statements about the decrease or the disappearance of the blood group ferment following irrigation of the oral cavity. A comparative constancy of the content of the saliva in A substance could likewise be corroborated. Further experiments were made to determine whether the disappearance of the blood group ferment leaves the diastase action of the saliva unimpaired. It was found that, whereas the blood group substance and diastase showed no decrease after breakfast but rather an increase, the blood group ferment decreased greatly. This indicates that there is no connection between the action of the diastase and the blood group ferment. Examination of the saliva during various times of the day disclosed that the blood group ferment is either lacking or greatly decreased after meals, but that it again increases to its maximum within four or five hours. The strongest ferment action could be demonstrated in the saliva taken while the person was still fasting. The author observed further that all persons whose saliva was examined had blood group ferment, although the action was not demonstrable in every experiment. Moreover, the amount of ferment may vary in the same person even if the specimens have been withdrawn under the same conditions. In other experiments it was observed that specimens of saliva that influenced heated A saliva always destroyed the A substance in Witte's peptone, but that, on the other hand, the blood group ferment action was occasionally directed only against the A substance in Witte's peptone without exerting a noticeable influence on that of the saliva. This proves that Witte's peptone is a more susceptible A substrate for the blood group ferment than is the saliva.

Diagnosis of Lead Poisoning in Children.—Kasahara points out that in Japan lead poisoning of children is relatively frequent. This is due to the fact that the powders used by the mother as well as for the nursing often contain lead. Children develop two types of lead poisoning: (1) lead anemia and (2) lead poisoning with meningeal symptoms. The first type is characterized by the following symptoms: anemia, restlessness, irritability, biting at the nipples, lack of appetite, loss of weight and occasionally nausea and vomiting. The lead line on the

gums is hardly ever demonstrable, but the teeth occasionally have grayish black or black deposits. The finger and toe nails have been known to turn black. Hematoporphyrinuria hardly ever develops, and the urine does not contain urobilin or urobilinogen. The hemoglobin is decreased, as are also the erythrocytes. Moreover, there is a considerable increase in the number of reticulocytes, and erythrocytes with basophil granules appear. In the severer cases poikilocytosis, anisocytosis and polychromasia develop. In lead poisoning with meningeal symptoms there develop, in addition to the signs mentioned those indicating pressure on the brain, manifested by protrusion or tightly stretched fontanels, tremor of the hands, convulsions, impairment of consciousness and gnashing of the teeth. The cerebrospinal fluid shows increased pressure, xanthochromia, increased protein and globulin content, slightly increased sugar content and lymphocytosis. The second form develops primarily during the warm season. Blindness due to atrophy of the optic nerve has been known to develop as a sequel. The mortality rate is about 33 per cent. The diagnosis rarely gives difficulties. The author, searching for the bandlike shadows at the end of the long tubular bones, found that these shadows are demonstrable not only on the end of the long, tubular bones but also on the shorter bones, on the flat bones and around the centers of ossification. He calls attention to the skin reaction suggested by Lewin for the diagnosis of lead poisoning and describes a modification that he found helpful. For examining the blood for the presence of basophil granules the author used the method of Manson, but he emphasizes that the hydrogen ion concentration of the dye solution is important. He found that, if Manson's method is used, a pH of 5.54 is most satisfactory.

Follicle Maturation Hormone and Estrogenic Substance in Urine During Skin Diseases—Bohnstedt observed increased elimination of the active principle of the anterior hypophysis and of estrogenic substance, respectively, in several dermatoses, but he thinks that so far the elimination of these substances may be considered significant only in acne rosacea. The urine of two patients with symmetrical dysmenorrhoeal dermatitis contained greater amounts of the follicle maturation hormone. However, in four women with eczema in whom the cutaneous manifestations became exacerbated during menstruation, estrogenic substance was not present in the urine nor could the follicle maturation hormone be detected in larger quantities. In case of hypofunction of the testicles as the result of inflammatory disturbances (orchitis fibrosa) or of atrophy, an increased elimination of the active principle of the hypophysis may become manifest. The author thinks that more general conclusions are as yet premature and that further investigations will be necessary.

Strengthening of Antithyroid Protective Action of Blood by Thyrotropic Hormone of Hypophysis—In former studies Eitel and Loeser showed that the thyroid activating effect of the thyrotropic hormone of the anterior hypophysis is no longer demonstrable following preliminary treatment with blood for approximately 1 cc. of injected serum was found to counteract the effect of one guinea-pig unit of the thyrotropic substance. Sheep's blood proved to be most effective. The authors show that the antithyroid protective action of the blood may be increased by preparatory treatment of the donor animals with thyrotropic hormone. They injected sheep daily for several weeks with 1,000 guinea-pig units of the thyrotropic serum. Specimens of blood were withdrawn on the thirteenth, twenty-first and twenty-eighth days and were examined. The first specimen revealed a considerable increase and after four weeks of treatment the antithyroid protective

action of the blood was six times as great as before the injections of the thyrotropic substance. Preparatory treatment with thyroxine was found to work no changes in this respect, and the blood of patients with exophthalmic goiter likewise was found to have no essential protective action. The antithyrotropic substance is contained in the serum and in small quantities also in the corpuscles. The site of formation of the antithyrotropic substance is still unknown. It can hardly be in the hypophysis, for the oral administration of large amounts of dried anterior hypophyseal tissues does not counteract the thyroid activating action of the thyrotropic hormone. Moreover Anderson and Collip found that the blood of hypophysectomized rats even contains the antithyroidal principle.

Vitamin A and Cholesterol Metabolism—Collazo and his associates demonstrate that vitamin A exerts a great influence on the cholesterol metabolism. They found that in rats with A avitaminosis the cholesterol content of the serum as well as of the organs is considerably reduced, while in rats with A hypervitaminosis it is increased.

Indications for and Results of Short Wave Therapy in Surgery A. Lob—p. 1812

Therapy of Pulmonary Infarcts—Meissner points out that Trendelenburg's operation for pulmonary embolism, although quite successful in suitable cases, should be resorted to only in rare instances. Then he discusses the smaller embolisms that are not immediately fatal. If the embolism occurs in the peripheral portions of the lung hemorrhagic pulmonary infarcts develop and the ensuing symptoms are dyspnea, anxious facial expression, profuse sweating, rapid pulsation, eventually cyanosis and piercing pleural pain that radiates upward into the shoulder. Annoying continuous hiccup develops quite frequently in such cases. The temperature does not rise high, but an irritating cough develops and, if the infarct is rather extensive the patients have a hemorrhagic sputum. Since the most painful symptoms are due to irritation of the phrenic nerve, the author treats these cases by anesthetization of this nerve. He uses from 15 to 20 cc. of a 1 per cent solution of procaine epinephrine. The anesthetization of the phrenic nerve always results in a considerable reduction or complete cessation of pain and produces considerable improvement. The diaphragm is more or less immobilized and the danger of a new embolism is greatly reduced. The pain conduction is interrupted, the patient becomes quieter, the respiration is more free, the hiccup disappears, the hemorrhagic sputum is more easily ejected and swallowing of food is no longer painful.

*Functional Disturbances of Female Sex Organs Following Artificial Abortion N. Kakuschkin—p. 2793

Sterilization by Destruction of Interstitial Portion of Tube—Scheffek destroys the interstitial portion of the tube by electrical coagulation. The abdomen is opened by a transverse fascial incision, the length of which does not have to exceed 7 cm. even if the layer of abdominal fat is considerable. The tube is severed transversely at its junction with the uterus. A thin electric needle is then introduced into the lumen of the tube and the interstitial portion of the tube is destroyed down into the uterine cavity. Then the needle is introduced into the lateral portion of the tube and the tubal canal is destroyed. The author employed this method in 182 women. It proved

successful in spite of the fact that the majority were unruly, insane women in whom it proved impossible to enforce post-operative rest

Disturbances of Sex Organs Following Artificial Abortion—Kakuschkin reports observations on 1,921 women. He cites statistics indicating that hardly one sixth of the women remain free from abortions, that more than four fifths resort to artificial interruption of pregnancy, and that more than one fourth interrupt all their pregnancies. The average number of abortions for each woman was 2.34, while the average of normal deliveries was only 1.87. In evaluating the influence of abortion on the function of the female sex apparatus the author considers fertility, menstrual function and libido. He found that over 50 per cent became sterile; that is they did not become pregnant for more than two years following the abortion. Examination of the women who had become sterile following abortion revealed inflammatory changes in the uterine adnexa, inflammations in the pelvis, catarrhal processes in uterus and vagina, atrophic processes, pathologic position of the uterus, deficient development of uterus and vagina and neoplasms in the uterus and ovaries. It is of course not certain whether all these changes were the true causes of the sterility in the different cases. He assumes that other changes, for instance those in the secretory function, may cause the sterility. Disturbances in the menstruation were observable in 150 cases. The libido was reduced in a number of women. The author assumes that the reduced libido as well as other postabortive disturbances are the result of a hormone trauma.

Tumors of Linea Mediana—According to Istenko Cushing was the first to separate the group of tumors limited to the fourth ventricle of the brain and the vermis. Of the author's fourteen cases verified either at operation or at necropsy, four were tumors of the fourth ventricle, while ten involved the vermis with a partial extension into the cerebellum proper. The author considers the following as basic symptoms of the syndrome of tumors of the median line: 1 A characteristic posture of the head and at times of the entire body. He views this phenomenon as a complicated postural reflex rather than an adaptation to relieve the dynamic block in the ventricles. 2 Marked difficulty experienced by the patient in attempting to change from a horizontal to a vertical posture. 3 Dependence of headache on the change of position of the head. 4 Paroxysmal periodic character of the headaches. 5 Variability and inconstancy of certain symptoms as to their localization and intensity. 6 A number of cerebellar symptoms particularly of the vermis, without a definite unilaterality. The less characteristic symptoms are (1) seizures of tonic convulsions of decerebrate rigidity type, (2) diminution of tendon reflexes in the lower extremities, (3) papilledema, (4) Kernig's sign, (5) involvement of various cranial nerves, (6) pain in the back of the neck and tenderness along the occipital nerve, (7) failure to obtain fluid on cisternal puncture, (8) constant and pronounced hydrocephalus, (9) rather acute onset, rapid course, at times galloping, and (10) death characterized by respiratory paralysis. The author offers differential points in the diagnosis of tumors involving the fourth ventricle and those involving the vermis. The following are more characteristic for tumors of the fourth ventricle: periodicity of headaches, dependence of headache on the position of the head, production of symptoms on changing from the horizontal to the vertical position, involvement of cranial cerebral nerves, variability and inconstancy of symptoms and characteristic mode of death. In the tumors of the vermis the cerebellar symptoms are more marked than in those of the fourth ventricle.

Lesions of Central Nervous System Following Injections of Neoparsphenamine—Chetverikov and Kavyrshin report three cases in which symptoms of meningo-encephalitis developed after injection of neoparsphenamine. In two cases neoparsphenamine was administered for the treatment of malaria and in one for psoriasis. In the first case symptoms developed after a second dose, 0.45 Gm of neoparsphenamine, administered nine days after the initial dose of 0.3 Gm. In the second case, 0.6 Gm of neoparsphenamine was administered two days after the initial dose of 0.45 Gm. In the third case symptoms developed after the third injection of 0.6 Gm administered two days after the second injection. The clinical onset in the three cases was abrupt and stormy, suggesting a diffuse involvement of the entire central nervous system, a meningo-encephalitis. The symptoms were fever, headache, vomiting, general weakness, pain in the lower extremities, loss of consciousness, disturbances of the pelvic organs and involvement of the upper and lower extremities, with sensory disturbances and paresis of the cranial nerves. Such cases not infrequently terminate lethally. In the authors' cases the cerebral symptoms subsided in the course of from two to three weeks, the process remaining localized in the spinal cord and leading to paralysis of all the extremities or of only the lower ones. The subsequent course is chronic with a gradual but insignificant improvement in symptoms. The more marked symptoms are those caused by the involvement of the thoracic and the lumbosacral segments of the cord. The authors conclude that lesions of the spinal cord are more permanent than those of the brain. They believe that an increased permeability of the hemato-encephalic barrier is an important factor enabling neoparsphenamine to permeate the central nervous system. The condition of the vegetative endocrine apparatus as well as that of the metabolism and colloids play a part. The dose and the interval between doses are of significance for each case. The authors recommend the following prophylactic measures: 1 Maximal precautions must be observed in the presence of defective functioning of the vegetative endocrine apparatus. 2 The permeability of the hemato-encephalic barrier should be determined in all such cases. 3 The treatment in women must be interrupted in the premenstrual and menstrual periods. 4 Preference is to be given to small fractional doses, while the intervals between the doses must not exceed the established norms. 5 The injection of neoparsphenamine should be performed slowly.

Paraffin Therapy—According to Kirichinsky and his associates, the therapeutic value of paraffin is based on the physical qualities of this substance (contractibility, elasticity, conductivity of heat and so on), which make it fit for hot applications in certain diseases, principally of rheumatic origin. The founder of the paraffin treatment method was Barthe de Sandfort, who used it as early as 1910 in Paris. The authors have used it since 1932 in a somewhat modified form instead of pouring paraffin on the affected extremity, they put the member into liquid paraffin in a specially fitted box. This modification has the advantage of transmitting more heat to the tissues. Insignificant alterations of pulse and of body temperature are observed, the perspiration is more abundant as the sittings are repeated and this is accompanied by marked relief of pain. Every sitting lasts from one-half to one hour. The authors studied 200 cases treated according to this method and found a marked improvement of the condition in 80.4 per cent. In 11.6 per cent no changes were noted and in 3 per cent there was a change for the worse.

THE INFLUENCE OF THE CEREBRAL CORTEX ON GASTRO-INTESTINAL MOVEMENTS

JAMES W WATTS, M D
PHILADELPHIA

After the publication of Cushing's¹ address on peptic ulcers and the interbrain and Keller's² paper on ulceration of the digestive tract following experimental lesions of the hypothalamus, it seemed desirable to study the effects of hypothalamic lesions on the gastro-intestinal tract of monkeys. Since monkeys had not previously been used in such experiments it was essential that a careful study be made of their gastro-intestinal tracts under laboratory conditions as a basis for interpreting changes that might follow hypothalamic lesions.

For this purpose complete autopsies were performed on all animals (eighty in number) that died or were killed during the year 1932-1933 (at the Laboratory of Physiology at Yale University School of Medicine),³ attention being directed particularly to the intestine. In the course of these autopsies, intussusception with intestinal obstruction was found to be the cause of death in three otherwise healthy animals, all three intussusceptions occurred in monkeys that had been subjected to bilateral removal of parts of the frontal lobes (including the premotor area). Though suggestive of a relation between cortex and intestine these observations would in themselves allow no definite conclusions, even though in 300 primate autopsies obstructive intussusception had not previously been encountered (1930-1933). We⁴ were therefore led to investigate the influence on the gastro-intestinal activity exerted by the cerebral cortex. In the present paper a brief summary is presented of the results, with special reference to their clinical significance.

REVIEW OF THE LITERATURE

Stimulation—During the latter part of the nineteenth century, experimental evidence accumulated which indicated that the cerebral cortex influenced gastro-intestinal

movements. In 1876 Bochefontaine⁵ pointed out that faradic stimulation of the region of the sigmoid gyrus of the dog caused peristaltic contraction of the pyloric region of the stomach, followed by inhibition of the pylorus itself, and that sometimes such stimulation caused increased movements of the small and large intestines. Often peristalsis of the large intestine so induced was so forceful that it carried the fecal contents ahead of it. These observations were substantially confirmed by Hlasko⁶ and Openchowski⁷ and greatly extended by Bechterew and Mislawski⁸ and by Osipov.⁹ Bechterew and Mislawski found that stimulation of certain points near the cruciate sulcus gave rise to vigorous movements of the gastro-intestinal tract whereas excitation of others caused inhibition of these movements. Page May,¹⁰ who used both dogs and monkeys, was unable to confirm Bechterew's results. More recently Sheehan¹¹ has found that stimulation of the monkey's frontal lobe rostral to the motor area causes no effect on the "resting" (unfed) stomach but frequently leads to prompt inhibition of peristalsis in the "active" (fed) stomach.

Release—Only three years after Bochefontaine published his results, Ott and Field¹² observed that quiet peristalsis in the cat's intestine became very active after the brain had been sectioned posterior to the thalamus. Similar results were obtained by Bechterew¹³ and by Lurje,¹⁴ indicating that some part of the brain rostral to the section exerts an inhibitory influence on peristaltic movements. In view of the work of Cushing¹ and of Beattie and Sheehan,¹⁵ it is quite possible that the inhibitory influence may emanate to some extent from the hypothalamus, but the earlier studies on cortical stimulation, the more recent ones of Sheehan,¹¹ and the observations on experimental intussusception,⁴ indicate that the cortex also plays an important part in regulating and inhibiting the activity of the intestine.

EXPERIMENTAL RESULTS

Under light ether anesthesia, various parts of the cortex were stimulated faradically for periods of from

one to two minutes, precautions being taken to prevent the spread of the current.⁴ With the abdominal cavity open and the intestine floated in warm saline solution, the visceral organs were observed directly. When the premotor area was stimulated, a latent period of about twenty seconds usually elapsed before changes in the gastro-intestinal tract occurred. A marked increase in peristaltic activity of the cecum and lower part of the small intestine was generally the first change noted but in some animals striking 'peristaltic rushes' were initiated in the colon by such a stimulus. Vigorous peristalsis of the small intestine also occurred, but more often ringlike bands of contraction developed during application of the stimulus and these as a rule were not transmitted. The persistence of such sharply defined bands of contraction in one segment, aided by peristaltic waves from cephalad segments resulted in some instances in the invagination of the active portion of the intestine into the lumen of the passive segment lying in continuity with it. Often the intussusceptions so produced were multiple, usually formed in the ileum, and did not persist permanently, i. e., did not cause obstruction under the conditions of the experiment.

Vigorous intestinal movements could be produced by stimulation of many parts of the premotor area but not from every point within this area. The portion bordering on the superior precentral sulcus, from which Bucy and Fulton¹⁶ obtained ipsilateral movements of the extremities gave the most consistent increase in intestinal activity. Once activity had been aroused in the intestine by premotor stimulation, faradization of the prefrontal region and the postcentral gyrus sometimes caused augmentation of activity but primary stimulation of these regions in the intact cortex were without effect. In one animal from which the premotor area had been extirpated five months previously, stimulation of the prefrontal region and the postcentral gyrus caused a slight increase in peristalsis but never obstruction. In no experiment did stimulation of the motor area even when very strong influence movements of the intestine. In some experiments cortical stimulation caused increased secretion of gastric juice. Bilateral vagotomy abolished most of the cortical responses, though occasionally strong stimulation of the premotor area in such a preparation caused a slight increase in peristalsis. The consequences of sympathectomy were not studied.

COMMENT

Cortical Autonomic Epilepsy—The experiments just described suggest an explanation of the long recognized visceral symptoms and signs associated with focal seizures in man, especially those which occur in the absence of increased intracranial pressure. When pressure is increased, the symptoms of nausea and vomiting cannot be attributed solely to cortical derangement. In uncomplicated focal seizures, however, visceral phenomena may be of localizing significance. Watts and Frazier¹⁷ recently presented case histories of two patients in which manifestations such as nausea, epigastric distress and vomiting served to abort, or were substituted for, epileptic convulsions. In one instance, nausea followed by vomiting aborted individual focal seizures affecting the extremities. In the other instance several focal convulsions occurred early in the anamnesis, then fol-

lowed an interval of four years in which there were periodic episodes of nausea, epigastric distress and vomiting, but no convulsions. After four years the characteristic convulsive seizures were resumed.

In their study of the cerebral localization of epileptic manifestations, Penfield and Gage¹⁸ observed that an aura of pain or epigastric distress may arise from activity of the cerebral cortex. Under local anesthesia in conscious patients they found that stimulation of area 7a caused pain in the right lower quadrant of the abdomen in one case, and stimulation of the same area elicited an epileptic attack preceded by the usual epigastric aura in another.

The observations of Penfield and Gage¹⁸ established sensory autonomic representation in the cortex for the gastro-intestinal tract in man. The experiments of Watts and Fulton⁴ establish motor autonomic representation in the cortex for the gastro-intestinal tract in the monkey. Correlating these results with occurrence of epileptic manifestations such as nausea and vomiting, associated with focal epileptic convulsions or occurring alone as in the patients described, led Watts and Frazier¹⁷ to postulate motor autonomic representation for the gastro-intestinal tract in the cortex of man. It is probable, therefore, that nausea, epigastric distress and possibly vomiting may be the result of neuronal discharge from the motor autonomic portion of the cerebral cortex. We also believe that the epigastric aura and other abdominal sensations usually are not 'referred' sensations but rather the result of vigorous and probably abnormal, movements of the gastro-intestinal tract.

Morbid Hunger—Cases of morbid hunger following injury to the brain have been described by Paget¹⁹, Bechterew,²⁰ and Sollier and Delageniere.²⁰ In 1909 Spiller²¹ reported a case of glioma occupying the whole pons, in which intense hunger was a prominent symptom, and remarked that he had observed two other cases of brain tumor presenting this symptom. It was Spiller's impression at that time that the location of the tumor was not significant in relation to the production of excessive hunger. In the following case the sudden appearance of excessive hunger was one of the first symptoms in a patient who subsequently proved to have a frontal tumor.

A man, aged 45 with a right frontal lobe tumor, in whom the sudden appearance of a ravenous appetite was one of the first symptoms, was referred to the neurosurgical service a few months ago by Dr. William G. Spiller. Associated with the onset of excessive appetite in 1930 were increased thirst, increased libido and morbid somnolence. Two years later generalized convulsive attacks developed, which usually began with the turning of the head to the left. Profuse sweating with a very offensive odor perceptible to other people was noted after each attack. On examination the man was found to have bilateral choking of the optic disks but no cranial nerve palsies and no motor or sensory disturbances. A ventriculogram showed evidence of a right frontal lobe tumor. A huge meningioma in this region was exposed by Dr. Charles H. Frazier. Because of its extreme vascularity it was considered advisable to postpone its removal until a second stage, but unfortunately the patient died before this could be done. At autopsy the brain, which was examined by Dr. Bernard J. Alpers, revealed a very large, flat meningeal fibroblastoma,

firmly adherent to the dura mater. It occupied almost the entire right frontal lobe, extending from the falx cerebri to the orbital gyri. The tumor completely covered areas F¹ and F², except for a small area at the frontal pole, and compressed most of F³ and the precentral gyrus. The tumor could be separated from the brain only with difficulty. The under surface of the tumor was softened and necrotic, and the entire frontal lobe under the tumor was softened.

Two years ago Fulton, Jacobsen and Kennard²² noted that monkeys after bilateral removal of the frontal areas ate several times as much as normal animals. In the belief that the ravenous appetite might be due to some metabolic disturbance Bruhn²³ studied the basal metabolic rate of these animals as well as of normal monkeys. Bruhn's results soon made it apparent that in spite of their excessive appetites and activity these animals had a normal basal metabolic rate. However, he found that the basal metabolism may be elevated after bilateral premotor extirpation, presumably owing to spasticity of the extremities. In a recent discussion of morbid hunger, Fulton²⁴ said: "In view of the abnormal peristalsis of the gut resulting from these cortical lesions, it appears to me logical to suggest that symptoms of morbid hunger may be due to increased motility of the stomach and that the cases of morbid hunger reported in the literature may also be attributed to this circumstance." This offers an explanation based on experimental evidence of a symptom that has long been a medical curiosity. It might be added that a part of the excessive appetite and the tendency toward emaciation may be the result of food being hurried through the alimentary canal at a rate that does not allow time for digestion and absorption to be completed.

SUMMARY

1 Removal of cortical influence by extirpation of both premotor areas results in increased peristalsis and in some instances in intussusception. Faradic stimulation of the premotor area and certain adjoining parts of the cerebral cortex initiates vigorous movements of all parts of the intestine. Evidence is given indicating that cortical representation for the gastro-intestinal tract contains both excitatory and inhibitory components.

2 Epigastric aura and other visceral sensations associated with focal convulsive seizures or occurring independently usually are not so-called referred sensations but result from vigorous and perhaps, abnormal gastro-intestinal movements.

3 Morbid hunger associated with brain tumors, cerebral vascular disease and accidental injury to the brain is probably due to irritation or destruction of the intestinal representation in the cortex, or of tracts arising there.

University of Pennsylvania Hospital

ABSTRACT OF DISCUSSION

DR THOMAS J. HELDT, Detroit. In giving consideration to autonomic representation in the cerebral cortex, I suppose that this study may be regarded as dealing primarily with the preganglionic system of cells and fibers or of their equivalents. What are the details of postganglionic expression and how much thought has been given to stimuli more complex than those mentioned? Reference has been made to electrical stimulation and to stimulation by drugs. How much study has been

made of the more complicated sensory stimuli and the psychic factors that are so difficult to rule out and to separate at the time of stimulation by simpler methods? I am wondering whether Dr. Watts has given special study to such factors as might be involved when a securely leashed dog is presented with food just out of reach. Multiple stimuli are certainly at hand. To what extent is such a complex sensory stimulus comparable to electrical stimulation? This is probably a relative matter, but how much of a discount must be allowed for such relative and complex stimuli in the full explanation of the functions and the cerebral representations under consideration? On the basis of the reflex arc response and the postganglionic innervation of viscera, what are the possibilities of a "short circuit" and how much "short circuiting" is possible without actual central and precentral representation?

DR JAMES W. WATTS, Philadelphia. I agree with Dr. Quigley that one cannot say that movements of the gastro-intestinal tract are increased simply because there is an increase in appetite. As I said before conclusions cannot be drawn from clinical cases of ravenous appetite associated with cerebral lesions unless other factors have been excluded. In reference to one of Dr. Heldt's remarks I may say that all the experiments were done under light ether anesthesia. On several occasions when the anesthesia became light and the animal struggled vigorous peristalsis occurred in the large intestine when ether was reapplied. I do not know what to attribute this to, whether fear or the emotions played a part. However, I do not think such peristalsis is related to the associated activity of the skeletal muscles because repeatedly stimulation of the motor area (area 4) has elicited the usual vigorous movements of the extremities but no movements of the gastro-intestinal tract.

UPPER MOTOR NEURON LESIONS

AN ANALYSIS OF THE SYNDROMES OF THE MOTOR AND PREMOTOR AREAS

J. F. FULTON, M.D.

NEW HAVEN, CONN.

AND

HENRY R. VIETS, M.D.

BOSTON

When confronted by a patient exhibiting loss or impairment of voluntary power a clinical examiner sets about at once to determine whether the disturbance is in the muscles themselves or in the nervous system. The case history generally indicates which one is involved and if the trouble proves to be nervous in origin, the next step is to decide whether the central or peripheral nervous system is primarily concerned. In current neurologic teaching a broad distinction is made between the paralyses resulting from lesions of the "lower motor neuron" and those due to interruption of the "upper motor neuron." The lower motor neuron has its beginning in the cells of the anterior horn and its ending in the skeletal muscles. The term upper motor neuron has reference to the pathways from the cerebral cortex conveying volitional impulses, directly or through intermediate neurons, to the anterior horn cells of the spinal cord.

The symptoms of lesions of the lower motor neuron, such as occur in poliomyelitis, are identical with those produced by cutting a motor nerve, i. e., voluntary power is completely destroyed in the affected muscles, reflexes are abolished, the affected extremity is flaccid and electrical stimulation reveals the typical "reaction of degeneration" (table 1). Contractures and other

B Premotor Lesions—Following isolated removal of the premotor area, profound motor disability occurs, which lasts, both in man and in the chimpanzee, for four or five days. Immediately after such a lesion, however, the affected extremity becomes highly spastic, no wasting occurs, electrical excitability is normal, and certain characteristic pathologic reflexes, such as forced grasping, the fanning sign of Babinski and the signs of Rossolimo, Mendel-Bechterew and Hoffmann, develop (table 3). There is also profound vasomotor disturbance, the affected extremity losing for a time its power of reflex vasodilatation and sweating.⁹ Voluntary power begins to return simultaneously in all parts of the extremity, generally from four to five days after the lesion, but skilled movements, such as those necessary to play the piano, to "finger" a violin or to tie a shoe-lace, become permanently impaired and the impairment can be demonstrated long after such a lesion has occurred. Spasticity, forced grasping and vasomotor disturbance, however, tend to disappear with the return of voluntary power.¹⁰ In chimpanzees these symptoms reappear in all four extremities when a premotor lesion is made in the opposite hemisphere. This indicates the existence of bilateral representation in each hemisphere.¹⁰

Following premotor lesions there is some "intellectual" deficit in that the "memory" for acquired skilled movements is lost, but reeducation is possible.⁸

C Combined Motor and Premotor Lesions—When the motor and premotor areas are simultaneously removed from one hemisphere, the affected extremities are at first flaccid with depressed reflexes (pyramidal tract effects), but strong spasticity, reflex exaggeration and vasomotor disturbances are prone to develop within three or four days (nonpyramidal premotor effects). The signs of Babinski, Chaddock (pyramidal), Rosso-

The symptoms present in hemiplegia therefore are usually those of a combined motor and premotor lesion with both the pyramidal and nonpyramidal reflexes demonstrable.¹¹ The size and approximate position of the lesion may be estimated from the reflexes actually present, and from this some indication as to prognosis can be obtained, for if only pyramidal tract signs are exhibited the return of motor power will be more extensive than if the premotor reflexes are present as well, and, conversely, if only premotor reflexes are

present without pyramidal tract signs the ultimate prognosis is even better.

THE SYNDROME OF THE MOTOR AREA

It is thus possible readily to differentiate motor from premotor pareses on the basis of the specific reflexes indicated in table 3. The pure motor area syndrome, however, rarely occurs clinically, but it is seen following discrete gunshot wounds, occasionally from small sharply localized tumors, and it has been produced by neurosurgeons¹² in the treatment of athetosis and focal seizures (excision of cortical scars). The characteristics of the syndrome may be summarized as follows:

1 **Motor Power**—There is gross loss of motor power in specific muscle groups. Thus, if the motor area for the hand has been removed the digits are completely paralyzed for days or weeks, if the lesion is sharply restricted, motor power in other muscles of the same extremity, e. g., biceps or triceps, may be entirely normal. The focal character of motor area paralysis is their most striking characteristic. Foerster and Penfield,¹³ for example, describe paralysis of the interossei of two fingers produced by a tuberculoma the size of a pinhead in the finger representation.

2 **Focal Seizures**—With expanding lesions of the motor area, focal seizures of the jacksonian type are common. Such seizures begin characteristically with a single muscle group, such as the flexor of the index or hallux, and proceed to involve other muscles of the extremity in definite sequence. The "march" of symptoms in such cases often is exactly the same in all seizures. The motor area seizures thus stand in sharp contrast with the premotor, which begin with a complex pattern of movement generally involving a whole extremity.

3 **Reflex Changes**—These have been enumerated in table 3. They vary to a certain extent with the nature of the lesion. If a given area is surgically excised, all reflexes in the affected muscle are abolished.

TABLE 2—*Symptoms of Voluntary Paralysis*

	Upper Motor Neuron Lesions		Lower Motor Neuron Lesions (Anterior Horn Cells or Peripheral Motor Nerve)
	Pyramidal (Motor Area)	Nonpyramidal (Premotor Area)	
1 Rigidity	Flaccid or normal	Spastic	Flaccid
2 Deep reflexes*	Depressed at first	Greatly augmented	Abolished
3 Superficial reflexes (lower limbs)	Flexor exaggeration with Babinski	Extensor exaggeration	Abolished
4 Muscular atrophy	Marked	None	Very marked
5 Electrical reactions	Transient depression	No change	Reaction of degeneration
6 Contractures			
Lower limbs	Flexion	Extension	Irregular depending on treatment and on action of nonparalyzed muscles
Upper limbs	Slight and variable	Flexion and adduction	

* See table 3

limo, Mendel-Bechterew and Hoffmann together with the fanning sign of Babinski (nonpyramidal) are likely to be permanently present (table 3).

A capsular hemiplegia in man may destroy chiefly the motor pyramidal radiations (if at the genu) or chiefly the premotor radiations (if in the anterior limb), but there is much overlapping in the two projection systems as they pass through the capsule, and a vascular accident in this region generally destroys both systems.

for a variable period. If on the other hand, the lesion has been made by a gradually expanding tumor, the initial stage of reflex depression may be minimal or entirely absent. The only well recognized pathologic reflexes in the lower extremity associated with interruption of the pyramidal tracts are those of Babinski and Chaddock.

4 *Flaccidity*¹³—Resistance to passive manipulation of an extremity whose pyramidal control has been destroyed is generally less than normal and is certainly never increased. This is true despite the fact that some of the deep reflexes, such as the knee and the ankle jerk, may be exaggerated. Knee and ankle clonus are generally not demonstrable, and changes of resting posture with alteration of the position of the body in space do not occur. During the Great War, Head¹⁴ described cases of cortical "hypotonia" following shrapnel injuries of the postcentral convolution. Careful scrutiny of his case histories indicates that in all instances the lesion was adjacent to the central sulcus and therefore undoubtedly involved the motor area within the sulcus. In view of recent experimental studies it seems likely that the "hypotonia" in these cases is due, not to the postcentral involvement, but to the destruction of the motor area itself.

5 *Miscellaneous Symptoms*—There is no loss in the patterns of movement in motor area lesions, and if a specific muscle e. g., of the finger, is weak the remaining muscles of the extremity are capable of carrying out any previously acquired skilled movements with accustomed dexterity, which is in sharp contrast with premotor lesions. Similarly there is no vasomotor disturbance or other signs of autonomic involvement with motor lesions.

THE SYNDROME OF THE PREMOTOR AREA

The differences in the motor and premotor syndromes might be predicted on the basis of their differing response to faradic stimulation. Stimulation of the motor area gives sharply restricted focal responses, whereas stimulation of the premotor region evokes complex patterns of movement. In keeping with this isolated extirpation of the premotor area, or gradual destruction of it by tumor, gives rise to a series of disturbances that generally appear in clinical cases in the following chronological sequence.¹⁵

1 *Disturbance of Skilled Movements*—Appearing first in clinical cases and persisting longest after experimental lesions, disturbance of skilled movements may be regarded as the primary symptom of a premotor lesion. Long before any impairment of the grip occurs or of gross movements such as those involved in walking and climbing are found, awkwardness may be present and skilled acts such as those previously enumerated are rendered impossible. The deficit is then one involving the coordinated activity of the musculature as a whole.

2 *Seizures*—The seizures from premotor lesions begin similarly with a complex movement, generally with turning of the head and eyes to the opposite side ("adversive" seizures), followed by a complex pattern of movement affecting one or both extremities on the opposite side and often involving to a slight extent the extremities on the same side.

3 *Reflex Changes*—After skilled movements have become affected, deep reflexes become markedly increased, and such pathologic signs as those of Rossolimo, Mendel-Bechterew and Hoffmann generally develop (table 3).

4 *Spasticity*—With the appearance of the foregoing reflexes, the resistance of the extremity to passive manipulation gradually increases, and strong spasticity may ultimately result.

5 *Forced Grasping*¹⁶—A special manifestation appearing late in the anamnesis of clinical cases and disappearing early following experimental lesions is the prehension phenomenon generally referred to as "forced grasping." It is pathognomonic of a premotor lesion. If forced grasping is poorly developed it can generally be brought out by placing the patient in the lateral position with the affected extremity uppermost, which is the maximal position for the reaction. The Babinski response is generally not present, although lateral deviation of the toes may occur, occasionally exaggerated flexion of the toes is seen in response to plantar stimulation.

6 *Vasomotor Disturbances*¹⁷—The temperature regulation in the affected extremities after a premotor lesion may be disturbed, owing to paralysis of the mechanism for reflex dilatation and reflex sweating.

When lesions occur in the spinal cord or the brain stem usually both the pyramidal and the nonpyramidal components of the upper motor neuron are affected, and the mixed syndrome is the result. Upper motor neuron lesions of this type are even more complex than those originating in the cortex, since the subcortical motor projection systems are often involved along with cortical systems. But the subcortical extrapyramidal systems are of no concern in this paper, since in mature animals they do not mediate voluntary movements.

SUMMARY

Paralysis of voluntary movement may be due to lesions of either the upper or the lower motor neurons. The manifestations of lower motor neuron lesions are identical with those following section of a motor nerve. Manifestations of upper motor neuron paralysis are various, and in the past no attempt has been made to dissociate the symptoms produced by destruction of the pyramidal pathways from those produced by interruption of other voluntary projection systems from the cortex. Recent studies on the specific components of upper motor neuron lesions in monkeys, apes and man allow the following conclusions:

1 Lesions restricted to the pyramidal tracts or to their cells of origin cause flaccid motor paralysis, muscle atrophy, transient depression of all reflexes, and the positive signs of Babinski and Chaddock, after complete destruction of the pyramids, the signs of Babinski and Chaddock persist permanently, but the paralysis, flaccidity and reflex changes tend with time to disappear.

2 Lesions of the premotor projection area of the cortex, which also mediate voluntary movements, give rise to spastic paralysis, disturbance of skilled movements, forced grasping, vasomotor disturbances, increased deep reflexes and the signs of Rossolimo, Mendel-Bechterew

and Hoffmann. Forced grasping and vasomotor disturbances are transient but disturbance of skilled movements and the signs of Rossolimo and Hoffmann tend to persist.

3 Hemiplegia in man is generally produced by combined destruction of motor and premotor components of the upper motor neuron, and hence such cases generally exhibit combinations of the foregoing symptoms with more severe ultimate motor paralysis than when only the pyramidal tracts are involved. The prognosis can be inferred from the extent to which the two systems are involved.

ABSTRACT OF DISCUSSION

DR. I. S. WECHSLER, New York. The most outstanding sign of frontal lobe impairment is akinesia both motor and psychic. The akinesia is probably due to lack of attention, and so is the memory defect. Memory consists of attention, association, retention and recollection. The frontal lobe patient lacks the first element of memory. The next defect is inability to associate, hence the loss of recent memories. Another frontal lobe sign or symptom is loss of inhibition. From these defects derive some of the mental symptoms, although it is difficult to speak in psychiatric terms of frontal lobe syndromes. Heretofore acute flaccidity in hemiplegia used to be explained by shock, no one really knowing what "shock" means, and chronic flaccid hemiplegia by a parietal lobe lesion that is, by loss of tonus due to cortical or posterior column type of sensory impairment. If what the authors say is correct and I think it is, there is a better explanation. It may be that the flaccidity is due to the overactivity of the premotor area 6 when the motor area 4 is destroyed. The work of Olmstead and Warner showed the role of the frontopontocerebellar pathways on tonus stimulation of the cut fibers in decerebrate preparations induced flaccidity. The question of bilateral innervation is of importance because it throws light on bilaterality of signs in unilateral lesions. The usual explanation given is that the patient has more than one lesion. This is often true in vascular disease, but, if bilateral innervation is correct temporary and minor signs opposite to the paralyzed side may be due to impairment of ipsilateral fibers. As to grasping and groping experimental work points fairly conclusively to the frontal and premotor areas. I should like to suggest that the carphologia observed in infectious and other deliriums and in patients who show certain mental pictures is a grasping and groping phenomenon. The question of flaccidity and spasticity may throw light on the problem of hemiplegia in flexion and hemiplegia in extension. It may well be that the explanation lies in the involvement of different parts of the brain or different fiber systems. Thus, if the premotor area is affected, the hemiplegia is in extension, if the motor, the hemiplegia is in flexion.

DR. JOHN L. ECKEL, Buffalo. I have followed the work of these contributors for a number of years and feel that they are attacking this very complex problem in the only way that will insure accurate results. I agree with Dr. Bucy that the interpretation of symptoms from lesions due to a surgical condition, or resulting from disease of vessels, or any other process, is rather unsatisfactory. Some years ago Dr. Winkelmann and I endeavored to work out the origin and course of the frontopontocerebellar tract from pathologic material only, and our results were rather disappointing because of either too much destruction of tissue or of overlapping of lesions. The value of the work of these investigators is that they have established their syndromes experimentally and then correlate clinically in man as opportunity arises. Drs. Fulton and Viets had one or two clinical cases in man showing a premotor syndrome, which proves the point of their paper. If the authors would give the symptomatology and results of examination of that case it would help to fix the problem in the minds of those present. The great value to the clinician of this presentation is the table. When this appears in print one may carry it with him to the bedside and compare the symptoms of his patient with the chart, which will assist greatly in properly evaluating the symptoms at the bedside. The work of the authors clears up

many of the confusing symptoms and signs that one finds in various types and degrees of hemiparesis and hemiplegia. Their work leaves the thought with me that the vast majority of lesions will show combined symptoms. A purely focal lesion in area 6, resulting from gunshot wounds, a stab wound, a focal thrombosis or a small expanding lesion will show wholly premotor symptoms while those situated deeper in the brain at the capsule or in the spinal cord will of necessity show combined symptoms of motor and premotor area involvement.

DR. J. B. AYER, Boston. It is not uncommon to have a hemiplegia which, as time goes on, recovers unequally. The leg function will return rather better than the arm function, and both as a rule will be spastic in character. That is the usual picture, with the finer movements of the hand lagging behind the movement of the lower extremity. That perhaps can be explained by the authors' physiologic work. I have two cases in mind in which, after months in one and after two years in the other the arm remained absolutely inactive, and while not flaccid the reflexes are not very lively. There is a little atrophy, which perhaps might be secondary in type. The sensation is perfect. It is not a spastic arm in any sense of the word. The leg has become absolutely spastic. How is one going to explain that? One could think that from the physiologic analysis, area 4 has been completely obliterated so far as the arm is concerned, but not so far as the leg is concerned. Then the question of the premotor control comes in and it brings up a very important question. Is there localization in the premotor area? Can the premotor area pick out the leg area and omit the arm area in producing spasticity?

DR. WAITER FREEMAN, Washington, D. C. There are a few signs in patients with lesions of the frontal lobes that might also be observed in animals. In patients with slight lesions in the premotor area, and without disturbance of the motor area (apparently because there is no Babinski sign) one is apt to get a strongly positive Mayer sign. This is produced by forced flexion of the fourth finger, and the sign is the adduction and opposition of the thumb. In the same way, in the lower limb by tapping at the base of the toes one can sometimes produce a slight clutch reaction which is very much like that found in the infant. The authors and I suffer some disagreement, possibly, over the term "spasticity." Spasticity, as I understand it, is a condition in which there are pathologic reflexes and also the characteristic lengthening and shortening reaction that one finds ordinarily in the classic hemiplegia. In individuals presenting lesions in the premotor area on the other hand, one observes a condition of tonic preparation or tonic innervation, which of course is the main cause of the impairment of skilled movements. In cases of hemiplegia speaking of homolateral innervation, there is weakness of such muscles as the sternocleidomastoid and the lingual muscles on the homolateral side. Homolateral innervation is equally well shown during convulsive seizures in which, for instance, given a jacksonian seizure of the left side, the head turns to the left by a spasmodic contraction of the right sternocleidomastoid muscle, and in the same way the tongue is apt to be forced over toward the left and bitten on the left side, indicating that the right lingual muscle is in a state of convulsion.

DR. PAUL C. BUCY, Chicago. The work on the cerebral cortex being done in the authors' laboratory is constantly clarifying clinical problems. There is one that has not been mentioned to which I wish to draw attention—the flaccid hemiplegias of cortical origin. Such a paralysis is usually associated with sensory changes and atrophy. The lesions that give rise to these hemiplegias are in the region of the Rolandic fissure, involving the postcentral gyrus and area 4 but sparing area 6, the premotor area. The atrophy that occurs is probably not the result of "trophic" disturbance but rather an atrophy of disuse—disuse not only because of the absence of voluntary activity but because of the absence of reflex activity as well, practically no spasticity being present, as area 6 is still intact. In connection with the point Dr. Ayer brought up, it is common experience that in hemiplegia the lower extremity usually shows marked recovery, whereas the arm remains more completely paralyzed. This recovery has commonly been explained as due to the subsidence of edema and local vascular change about the more permanent area of damage in the internal capsule. And although this may play a minor role it does not

explain why the leg always recovers considerably whereas the arm recovers but slightly if at all. It would seem rather that the recovery of the lower extremity is due to innervation from the ipsilateral cerebral hemisphere, in which the lower extremity is much more extensively represented than the upper.

DR. HENRY R. VIETS, Boston. I should like to add a word in regard to this work on the premotor areas and its clinical application. Dr. Kennard, Dr. Fulton and I were able to work out, in one patient, a syndrome, which was referred to by Dr. Eckel. In that paper (*Brain* 57:69 [March] 1934) we described the syndrome of the premotor cortex in man. Many neurologists thought we were going pretty far in describing a syndrome based on one case. As a matter of fact, the physiologic experimental work and investigation of the literature and one or two other cases that we have seen seemed to build up a group of symptoms we could justifiably call a syndrome. That syndrome consisted of the loss of or the diminution of skilled movements, spasticity, vasomotor changes and forced grasping. Even the order in which I have given them is of some significance. The patient we studied most carefully happened fortunately, to have both a vocation and an avocation, which was of great help to us. His position was that of a shoe salesman, and his avocation was that of playing the piano. He noticed first difficulty in tying shoe laces. Loss of that skilled movement long preceded any other symptom. Finally there was difficulty in playing the piano, which of course is a very skilled movement. Then the syndrome proceeded through spasticity, followed, to be sure, by motor symptoms of the convulsive type, with vasomotor changes and very marked forced grasping in one hand. A removable tumor was found at operation, and since that time (it is now nearly a year) these symptoms have gradually decreased in the opposite order. He began to lose his forced grasping fairly early, then the vasomotor changes disappeared, and finally the spasticity, and now the patient reports that his only difficulty is in using his left hand to play the piano. That, of course, was a very enlightening case and seemed to justify our speaking of the premotor syndrome in man.

DR. J. F. FULTON, New Haven, Conn. I agree with Dr. Wechsler that flaccidity of cortical origin is probably due to the unopposed action of the premotor area and that the predominant action of the premotor area on the lower center is one of inhibition. When therefore this area is removed, the reflexes that underlie the spastic state are released and the manifestations of decerebrate rigidity and the reflex changes associated with it develop. Dr. Ayers' question has been answered in part by Dr. Bucy, but it raises a more fundamental problem of whether there is a predominance of representation in the premotor area. We have no experimental evidence as yet bearing on the point, but I think it highly probable that the superior part of the premotor area has more to do with the lower extremity than the inferior part, which, presumably, being opposite the hand area, is predominantly associated with the more highly developed integrations of the upper extremity. Dr. Freeman has raised the question of Mayer's reflex. We purposely omitted Mayer's reflex from the table because we were not quite sure about it. It is probably a premotor reflex, but the data available do not permit us to say this with certainty for the experimental animal. The clutch reflex, hyperflexion of the toes, which is very similar to forced grasping as seen in the hand, is clearly a premotor phenomenon. We frequently see hyperflexion of the toes in response to plantar stimulation after removal of the premotor area, which is almost certainly the same phenomenon. Dr. Freeman has referred to the stimulus for this work has been throughout a clinical stimulus, and discussions such as we have had provide a great incentive to carry the work forward.

Coronary Thrombosis—It is recognized that the proximal inch of the left coronary artery and its descending branch is the favorite region of localization of coronary atherosclerosis in its most extreme form. THE ADVANTAGES OF PARALDEHYDE AS A BASIC AMNESIC AGENT IN OBSTETRICS

E. D. COLVIN, MD

AND

R. A. BARTHOLOMEW, MD

ATLANTA, GA

Analgesia and amnesia are worthy objectives in obstetrics, provided the agents used are safe and do not lead to uterine inertia and unwarranted interference, with resulting increase in maternal and fetal morbidity and mortality. Analgesia has been attained with a fair degree of success by the use of morphine, nitrous oxide, ethylene and ether or chloroform, each agent being used at the time most appropriate for it during labor. Amnesia is of more recent interest and development. That it is a worth while objective admits of no argument.

The average patient will not openly confess the apprehension with which she approaches labor, and the average physician does not appreciate the shock sustained by the nervous system. If a suitable amnesic agent or combination of agents can be found which will properly satisfy the strict requirements pertaining to labor, analgesia need not be perfect as long as the patient retains no memory of her suffering, for to her the labor has been painless.

Numerous amnesic agents and methods have been proposed and used in recent years, but the continued search for new methods indicates that such fundamental objections as tendency to uterine inertia, undue restlessness and excitement, interference with fetal respiration at birth, technical difficulties or possible harm to mother or baby, have interfered with widespread adoption of any one method. As a rule, any method of amnesia increases the need for assistance to terminate the second stage of labor, owing to the fact that the reflex, involuntary expulsive efforts alone are not as efficient as when reenforced by voluntary efforts. Any attempt to encourage voluntary efforts may so arouse the patient that amnesia will not be complete.

REQUIREMENTS OF SATISFACTORY ANALGESIA AND AMNESIA IN OBSTETRICS

There are certain fundamental requirements to which any proposed method of amnesia and analgesia should conform. To satisfy these requirements, it is often best to use two or more agents in combination whereby certain advantages may be enhanced and certain objectionable effects may be minimized.

Concerning the mother, there should be safety, a minimum of uterine inertia, preservation of reflex expulsive efforts, a minimum of excitement and no tendency to postpartum hemorrhage.

Concerning the baby, there should be safety and a minimum of interference with the establishment of respiration at birth.

Concerning the method, it should be simple, adapted to home as well as to hospital confinements, rapid in action, prolonged in effect and possess a wide margin of safety between the therapeutic and the toxic dose.

Read before the Section on Obstetrics, Gynecology and Abdominal Surgery at the Eighty-Fifth Annual Session of the American Medical Association, June 14, 1934.

INTRODUCTION OF PARALDEHYDE IN OBSTETRICS

It occurred to one of us (E. D. C.) in 1930 that the well known properties of paraldehyde, namely, a wide margin of safety rapid absorption rapid action and prolonged hypnotic effect with rarely any excitement or effect on the medullary centers, should make it a very desirable amnesic agent in obstetrics. At that time a review of the literature showed no reference to its use in obstetrics. No steps were taken to test its merits until the summer of 1933. At that time another review of the literature revealed a preliminary report by Rosenfield and Davidoff¹ based on the use of paraldehyde combined with pentobarbital sodium or sodium amytal in fifty cases. They reported complete amnesia in forty-seven cases and partial amnesia in three cases. There were no failures. There was no prolongation of labor, but this may have been due to the fact that delivery was accomplished by the prophylactic application of low forceps in forty-four cases, by midforceps in five cases and by internal podalic version in one case. To these authors should be given the credit for introducing paraldehyde as an amnesic agent in obstetrics.

In our own series of 100 consecutive cases we used paraldehyde as the basic amnesic agent in synergistic combination with sodium amytal and depended on nitrous oxide and ether for analgesia and anesthesia during the latter part of labor and at delivery. In nulliparas in whom the condition of the cervix and the character of the pains suggested a probable slow labor, morphine and scopolamine were used in addition to sodium amytal early in the first stage. All the women in the series were private patients and under personal supervision throughout labor.

We purposely avoided terminating labor with forceps, except in cases in which a real indication existed such as undue prolongation of the second stage or the presence of some emergency. It would seem that a high incidence of forceps delivery would not furnish as thorough a test of the amnesic effect of the method as a natural termination of labor with the help of the patient's expulsive efforts. Rosenfield and Davidoff preferred to use $7\frac{1}{2}$ grains (0.5 Gm.) of pentobarbital as a preliminary to the administration of from 4 to 6 drachms (15 to 22.5 cc.) of paraldehyde. In our own series we used 6 grains (0.4 Gm.) of sodium amytal on account of a more prolonged effect and a lessened possibility of uterine inertia, and followed this with from 6 to 8 drachms (22.5 to 30 cc.) of paraldehyde.

FACTORS DETERMINING TIME TO BEGIN TREATMENT

It is of the greatest importance in this as well as in any other method of obstetric amnesia and analgesia that each case be individualized on the basis of (1) parity, (2) degree of effacement and dilatation of the cervix, (3) frequency and duration of the pains and (4) whether or not the membranes are ruptured, these factors being listed according to their importance.

If the patient is a multipara, delivery will probably occur within the average duration of the effect of the injection which is usually from five to seven hours, whereas if she is a nullipara, the injection will have to be delayed until more progress has been made or else repeated before labor has terminated.

The degree of effacement, dilatation and softening of the cervix is more to be relied on in estimating the probable duration of labor than the pains.

Since many labors are characterized by considerable inertia in the first stage, it is important to withhold all medication until the pains are less than five minutes apart and of at least forty-five seconds duration. To begin any method of relief with pains occurring at intervals of from five to ten minutes is to invite inertia, prolongation of labor, discouragement of the patient and unwarranted interference. Furthermore, the patient, particularly the nullipara, will better appreciate what has been done for her if she is permitted to experience strong pains and make definite progress for a short period before being made oblivious to the most difficult and painful part of the labor.

Rupture of the membranes tends to insure better pains and progress, but if done artificially, it should usually be postponed until the cervix is at least one half dilated and the head is well fixed in the pelvis.

Hence, any one or more of the factors of multiparity thin soft cervix, frequent severe pains or ruptured membranes lessens the possibility of inertia developing after the treatment has been given.

Since the condition of the cervix is so important from the standpoint of when and how to administer the treatment, it will be found of great advantage to be able to follow the progress of labor accurately by rectal rather than by vaginal examinations. Rectal examinations may be made more often, conveniently and safely and it one will follow the sequence of rectal then vaginal, and finally rectal with each examination in labor, the technic will not be found difficult to acquire and it will seldom be necessary to make vaginal examinations.

In any case, if rectal or vaginal examination shows that the cervix still has some length or that the cervical rim is still thick, not fully softened and not dilated more than from 1 to 2 cm., it is best to withhold all medication even if the pains occur at less than five minute intervals. This will not deprive the patient of any necessary relief at this stage of labor and will avoid aggravating a possible uterine inertia which has not yet become manifest.

THE TECHNIC OF TREATMENT AND MANAGEMENT IN NULLIPARAS

When the pains are less than five minutes apart and last for from three-fourths to one minute and the cervix is thin and dilated from 2 to 3 cm. 3 grains (0.2 Gm.) of sodium amytal may be given. If within from one-half to one hour, satisfactory progress continues and cervical dilatation has increased to from 4 to 5 cm., the second dose of 3 grains of sodium amytal may be given, to be followed within one-half hour by the rectal injection of paraldehyde.

If, however, there is very little increase in cervical dilatation after the first dose of sodium amytal the second dose should be withheld, and if progress continues to be slow but painful one-sixth grain (0.01 Gm.) of morphine and $\frac{1}{300}$ grain (0.0002 Gm.) of scopolamine in 1 cc. of 50 per cent solution of magnesium sulphate may be administered, which will usually give ample relief for several hours. Cervical dilatation will then probably be sufficient to give the second dose of 3 grains of sodium amytal followed by the rectal injection of paraldehyde one-half hour later.

In other words, in nulliparas we prefer to obtain cervical dilatation of from 5 to 6 cm. with the preliminary dose of 6 grains of sodium amytal and the occasional use of one-sixth grain (0.01 Gm.) morphine and $\frac{1}{300}$ grain (0.2 mg.) scopolamine before giving the

¹ Rosenfield, H. H. and Davidoff, R. B. A New Procedure for Obstetrical Analgesia. *New England J. Med.* 207: 366 (Aug. 25) 1932.

rectal injection of paraldehyde. Certain patients will normally show more or less uterine inertia, with no medication whatever, and to administer the complete treatment too early in labor may result in the patient going to sleep, making little or no progress and waking up, later on, disappointed to find that she is still undelivered. The hypodermic injection of morphine and scopolamine should not be given if delivery is anticipated within several hours on account of the depressing effect on the infant's respiration at birth, hence its use is practically limited to nulliparas. The preliminary and complete dose of 6 grains of sodium amytal seems to be more essential than the morphine and scopolamine in securing complete amnesia with paraldehyde.

From one-half to one hour after the full dose of sodium amytal has been given, the rectal injection of paraldehyde should be given, provided there is no evidence of uterine inertia. The bladder should be emptied at this time. An enema at the onset of labor is advisable in all cases to insure thorough emptying of the lower bowel and to facilitate retention and absorption of the paraldehyde.

From 6 to 8 drachms of paraldehyde is mixed with an equal amount of olive oil, a thorough mixture being obtained by alternately drawing up and expelling the solution with a 50 cc syringe, fitted with an ordinary adapter to facilitate attachment of the rectal tube. Sufficient air is drawn into the syringe in addition to the mixture to expel the solution, which would otherwise remain in the rectal tube. The tube should be sufficiently soft and flexible to prevent injury to the bowel wall. The larger dose (8 drachms) is preferable, since there may be some waste during injection or some expulsion after injection. Sufficient solution should be expelled from the syringe almost to fill the tube, but it should not be allowed to escape.

The injection should be made just after or between pains, never during a pain with the patient lying in the left lateral or dorsal position, preferably the latter. The index finger should be inserted with the tube to guide it under the baby's head somewhat beyond the full length of the finger. Retention and absorption are not as satisfactory if the injection is made too low in the rectum. Rotation of the tube will remove any kink or obstruction. The injection is made within half a minute and the tube is quickly withdrawn. Gauze is placed against the anus at once to prevent expulsion of the solution, the patient being turned onto her left side and cautioned to avoid straining efforts. Constant pressure against the anus is maintained for from twenty to thirty minutes, at the end of which period the patient is usually asleep and has ceased attempts to expel the solution. She may then be turned onto her back and the pressure discontinued.

It is best to refrain from rectal examination for at least one hour after the injection in order to avoid the risk of expulsion of some of the solution during the examination, progress being judged by abdominal examination, expulsive efforts and inspection of the perineum.

THE TECHNIC OF TREATMENT AND MANAGEMENT IN MULTIPARAS

Whereas in nulliparas the main problem is to withhold the rectal injection until there is sufficient progress and no evidence of primary inertia, in multiparas the main problem is to see the patient in the home or hospital early enough to give an enema and obtain the desired effect from sodium amytal and paraldehyde

before labor has progressed too far. For this reason it is important to instruct the multipara in the latter part of pregnancy to report at once any show of blood, discharge of water or onset of regular pains occurring at intervals of not less than ten minutes.

If the cervix is not fully effaced or softened and not dilated more than from 1 to 2 cm, it is best to delay treatment until it is evident that there will be no inertia. When the cervix becomes thin and is dilated from 2 to 3 cm, 6 grains of sodium amytal may be given at once if the pains are severe, but it is given in two doses of 3 grains each at an interval of from one-half to one hour if the pains are less severe and the progress is slow. If quick action is desired, the powder may be given without the capsules. The most desirable time to administer the rectal injection of paraldehyde in the multipara is when the cervix is fairly thin and dilated from 3 to 4 cm. If the membranes have already ruptured, the treatment may be given earlier, as there is less chance of uterine inertia. If the cervix is fully dilated and the head is low in the pelvis when the patient is first seen, delivery will usually occur too soon for the injection to take effect. However, if the cervix is from one-half to two-thirds dilated, especially if the membranes are unruptured, the full dose (6 grains) of sodium amytal may be given at once, and if the patient is delivered before the rectal injection can be given or take effect, no harm will have been done.

The technic of the injection and the subsequent management is the same as that given for nulliparas. Nitrous oxide will often suffice for delivery, otherwise light ether anesthesia depending on the degree of relaxation of the perineum, may be used. If precipitate delivery is threatened before the patient can be moved to the delivery room, ether may be given to retard progress until the patient can be moved and properly prepared. Solution of pituitary may then be given to offset the effect of the ether.

EFFECT OF THE INJECTION OF PARALDEHYDE

The first effect of the injection of paraldehyde may be a slight burning sensation and a desire to expel the solution. From five to ten minutes after the injection hiccups may be noticed. From ten to fifteen minutes after the injection the patient begins to doze lightly between pains and the odor of paraldehyde may be detected on her breath. From twenty to thirty minutes after the injection she is usually sound asleep between pains and may have snoring respiration. During the pains she moves her arms and legs sluggishly and may turn from side to side but makes little or no sound. The eyes remain closed or occasionally open momentarily without any apparent focusing of attention. At times she may make some fairly rational remark concerning the pain or her surroundings but as a rule her words are unintelligible or concern events that have no relation to labor, thus showing a definite disorientation. She usually seeks a comfortable position on either side, which at times seems to be responsible for slight inertia but pains usually continue with the same frequency and duration, especially if she can be kept on her back. The pulse, respiration and blood pressure show no appreciable change. While nitrous oxide may be found helpful, it is not indispensable and the patient may continue without it until ether can be given during crowning. The baby cries promptly at birth and shows no change in its behavior after birth.

AIDS IN OBTAINING COMPLETE AMNESIA

Since complete amnesia is desirable, every effort is made to avoid stimulating or rousing the patient. From the time the rectal injection is given and the patient turned on the left side, she is shielded from bright light, the attendants are instructed to converse in low tones or whisper and all unnecessary noise is avoided. Members of the family or friends are cautioned against arousing the patient and they are usually content to remain outside the room. If the patient's position is changed it is done as gently as possible. It has been found helpful to cover the patient's eyes with gauze held in place by adhesive to lessen the chance of her comprehending the situation if momentarily awakened. This is particularly important before moving her to the delivery room. It is less disturbing to move her bed to the delivery room and lift her onto the delivery table. These precautions are carried out to insure better success with the patient who may be less susceptible to the drug and who might otherwise have so-called islands of memory throughout labor. Immediately after

2 to 3 minims of solution of pituitary may be given subcutaneously, provided there is no contraindication such as persistently slow fetal heart, abnormal position of the head, or contraction of the pelvic outlet, and also provided the patient is prepared for delivery. Episiotomy under local anesthesia may be sufficient if delay seems to be due to a rigid perineum. Failing in this, a low forceps delivery may be performed.

MANAGEMENT DURING AND AFTER DELIVERY

The nullipara is not moved to the delivery room until a slight degree of crowning is apparent, not only during but between the pains. The multipara may be moved when the head begins to cause bulging. To avoid undue disturbance, the bed may be moved into the delivery room and the patient lifted onto the delivery table. She rarely remembers being transferred to or from the delivery room and does not arouse during preparations for delivery. It is to be noted that these patients require much less ether than usual and show very little resistance to it. There is no tendency to postpartum hemor-

(a) This group includes sodium amytal (3 to 6 grains) morphine (one sixth grain) and scopolamine (½ grain) in 1 cc of 50 per cent solution of magnesium sulphate when indicated nitrous oxide and ether. This group includes forty three nulliparas and fifty-seven multiparas.

(b) This group includes sodium amytal (3 to 6 grains) paraldehyde (6 to 8 drachms) nitrous oxide and ether morphine and scopolamine when indicated. A group of forty three nulliparas and fifty seven multiparas.

(c) This includes pentobarbital sodium (7½ grains) or sodium amytal (6 grains) paraldehyde (4 to 6 drachms) nitrous oxide and ether.

(d) This includes pentobarbital (4½ to 6 grains) scopolamine (¼ to ½ grain) to be repeated as necessary nitrous oxide and ether in the expulsive stage.

delivery an intramuscular injection of morphine and scopolamine may be given if it is considered necessary to insure a period of several hours' sleep on return to the room. However, there will usually remain sufficient effect from the rectal injection to make this unnecessary. The family should be advised not to disturb the patient until she awakes.

AIDS IN OVERCOMING POSSIBLE INERTIA

Inertia developing during labor is not always due to the amnesic and analgesic effect of the treatment, as it is occasionally observed during the course of normal untreated cases. If it is present during the first stage of labor, artificial rupture of the membranes may be performed any time after the cervix is half dilated and will usually stimulate progress. Solution of pituitary may be dropped from a syringe into the patient's nose, to flow back over the mucous membrane. Definite response to the instillation is usually seen within ten minutes, and the possibility of a strong reaction is much more remote than with the subcutaneous injection. If there is undue prolongation of the second stage, from

rhage. On its return to the room, the bed is placed against the wall and chairs are placed alongside, which precaution is apparently unnecessary as the patient sleeps very quietly for several hours.

COMPARISON OF METHODS

Prior to the use of paraldehyde our method of relief was through the use of from 3 to 6 grains of sodium amytal early in labor, followed by nitrous oxide and ether. In nulliparas, morphine and scopolamine were often given intramuscularly following the sodium amytal.

It seemed best, therefore to compare the results obtained in 100 consecutive cases treated according to the outlined method with those obtained in an equal number of cases relieved by the addition of paraldehyde to these measures. In both series the cases were taken consecutively, with the exception of instances in which some complication, increasing the risk to the mother or baby, made it unfair to include the case.

The accompanying table presents a comparison of the two series, the series reported by Rosenfield and

Davidoff and the series in which the pentobarbital-scopolamine method was used² (apparently the method of choice with many obstetricians) in regard to the most important considerations involved in analgesia and amnesia and enables one to estimate the advantages or disadvantages of paraldehyde.

Comparing methods *a* and *b* in the table, it is seen that the addition of paraldehyde to the measures of relief formerly used resulted in no increase in the length of labor or the frequency of postpartum hemorrhage. There was a decrease in the frequency of uterine inertia and fetal apnea, but this is possibly due to the fact that morphine and scopolamine were used less frequently. There was a slight increase in the number of spontaneous deliveries and a slight decrease in the use of forceps. Solution of pituitary was used approximately three times as often, usually to hasten crowning and also to avoid the necessity of urging the patient to bear down. There was no maternal or fetal mortality. In two cases, intra-uterine fetal death had occurred before labor began, and the babies were born in a macerated condition. Since the paraldehyde given during labor had nothing to do with these stillbirths, they were properly disregarded.

Comparing methods *b* and *c*, it is seen that Rosenfield and Davidoff obtained 94 per cent complete amnesia and 6 per cent partial amnesia and had no failures, whereas we had 82 per cent complete amnesia, 16 per cent partial amnesia and 2 per cent failures. Under partial amnesia we include those patients who had one or more so-called islands of memory, such as remembering transfer to or from the delivery room, induction of anesthesia with ether or gas, noticing bright lights in the delivery room and restraint of the hands. There was no remembrance of pain. Therefore, these cases of partial amnesia, in which the memory of the most difficult part of labor is limited to one or more events of so little consequence, should properly be considered successful. Analysis indicates that such factors as prolonged labor, wherein the labor outlasts the effect of the drugs (from five to seven hours), failure to administer a small second injection (from 2 to 3 drachms), expulsion of some of the injection, too rapid progress after the injection, or inability to coordinate the administration of the drugs were responsible for failure to obtain complete amnesia. Had we resorted to delivery by routine forceps in these cases, as practiced by Rosenfield and Davidoff, many of the patients would have had complete amnesia through a shortening of the labor and a lessened degree of stimulation.

These factors that often interfere with obtaining complete amnesia may be controlled as one becomes more familiar with the technic and management. This is shown by the fact that the majority of cases of partial amnesia occurred in the first fifty cases in our series, whereas in the last fifty cases, forty-seven, or 94 per cent, showed complete amnesia.

Two cases in our series were designated as failures, not in the sense that they did not derive great relief from the treatment but only because the usual anesthetic effect was not obtained. These patients were probably more or less immune to the drugs used, an idiosyncrasy that may be found in the use of any drug. It is therefore possible to obtain complete amnesia in from 90

to 95 per cent of all cases and to afford great relief to the small number who fail to obtain amnesia.

Since Rosenfield and Davidoff used forceps as a routine, it enabled them to administer the treatment earlier in labor and to disregard the possibility of inertia, thereby lengthening the period of amnesia before delivery. This probably accounts for the longer duration of amnesia before delivery, although it is difficult to account for the longer duration of amnesia after delivery in their series, especially since pentobarbital is supposed to have less prolonged effect.

In our series, a patient's behavior was considered to be normal if she slept quietly between pains, made no outcry and merely turned from side to side or moved sluggishly during pains. It is admitted that these patients tend to disarrange sterile drapings and get out of position on the delivery table to a greater extent than if they were awake, but they are not at all difficult to control. Patients showing restlessness did not attempt to sit up or make any outcry but showed more constant motion, not only during but between pains. Patients showing excitement sat up in bed at times, made considerable outcries and were in a state of constant activity. According to this standard, only 2 per cent of the patients showed excitement and 4 per cent showed restlessness in our series. Rosenfield and Davidoff reported restlessness in 8 per cent of their patients. We believe that restlessness is a manifestation of barbiturate and not of paraldehyde action and is increased in some patients of a nervous temperament. It is not present to a troublesome degree in this method of amnesia.

Comparing methods *b* and *d*, it is seen that the pentobarbital-scopolamine method results in a slightly higher frequency and a slightly longer duration of amnesia before delivery, with some apparent shortening of labor, although the latter may be partly due to the more frequent use of forceps. There is a much greater frequency of fetal apnea at birth when scopolamine is used, which may be of some concern to the attendant and family, although the low fetal mortality indicates that apnea is not, of itself, a serious symptom.

Although Irving³ states that any method of amnesia in labor should be strictly a hospital and not a home procedure, we see no reason why the less favored mothers who must continue to be confined at home should not have the relief offered by this method of amnesia. The physician will require no more assistance than is usually freely available to him in the average home confinements, the apparatus for administration is very simple, the drugs are inexpensive and readily obtainable, labor is not prolonged and the frequency of forceps delivery is not increased, there is no risk to the mother or baby, and since complete amnesia can be obtained in from 90 to 95 per cent of all cases, we believe that this method more nearly approaches the ideal method of amnesia in labor than any other in use at the present time.

CONCLUSIONS

1 Analgesia and amnesia are desirable objectives in labor provided they are compatible with physiologic labor.

2 Paraldehyde as a basic amnesic agent in combination with sodium amytal or pentobarbital approaches the ideal in satisfying the fundamental requirements pertaining to labor.

ABSTRACT OF DISCUSSION

DR HAROLD H. ROSENFELD, Boston I advocate attempting to secure complete relief of pain throughout labor and not merely of the last half because my experiences seemed to prove that this can be achieved without prolongation of labor and without any deleterious effects to either mother or baby. It is because I believe in complete relief that my larger dosage and earlier administration are somewhat at variance with the procedure advocated by Drs. Colvin and Bartholomew. I start medication as soon as labor is definitely established. The index for this is the regularity and character of uterine contractions, regardless of the height of the presenting part or the dilatation of the cervix. I frequently start medication with a floating presenting part and a cervix that is not taken up. I have found that once labor is definitely established its progress is not interfered with by pentobarbital sodium. The procedure is as follows: At the outset of definite labor, $7\frac{1}{2}$ grains (0.5 Gm.) of pentobarbital sodium is given in divided doses. This is followed promptly by 6 drachms (225 cc.) of paraldehyde in oil by rectum. This medication is usually sufficient to carry a patient through the average type of labor for six or seven hours. If patients show evidence of conscious suffering before this time, rectal examination is made to determine whether labor can be carried to completion with gas-oxygen inhalations. If the examination reveals that the patient still has several hours of labor, from $1\frac{1}{4}$ to 3 grains (0.1 to 0.2 Gm.) of pentobarbital sodium is given by mouth or by rectum. If this added dose of pentobarbital sodium fails to quiet the patient, from 2 to 4 drachms (75 to 15 cc.) of paraldehyde may be repeated by rectum. This will usually carry the average patient through a twelve or fourteen hour labor. Should labor be further prolonged, small amounts of pentobarbital sodium with or without paraldehyde may be repeated as necessary until the time arrives when she can be carried along to completion of labor with small amounts of gas-oxygen inhalations. Failure to repeat medication when necessary will result in increased restlessness and diminished amnesia. With this procedure I have found that there is no appreciable interference with the secondary forces of labor, as the patients, though asleep, bear down forcibly and usually bring the presenting part to the perineal floor. When the vertex reaches the perineal floor and partially crowns, I complete the delivery by the use of perineal forceps and episiotomy when indicated. The forceps in these instances is used to guide the head more carefully over the perineum and thereby conserve the patient's energy and pelvic floor.

DR H. F. KANE, Washington, D. C. I have used paraldehyde as the basic drug for securing amnesia and analgesia in labor in 250 cases. The safety factor for both mother and baby is of great importance. I have seen no untoward results. When the patient first complains of pain I begin to administer paraldehyde. I use no barbiturates but frequently give morphine, although many cases have been carried through labor with paraldehyde alone. If restlessness occurs, I occasionally administer one-fourth grain (0.016 Gm.) of morphine. I administer 1 cc. of paraldehyde for each 10 pounds (4.5 Kg.) of body weight of the mother. But that isn't enough. I add 2 or 3 cc., depending on the size of the patient. It is a little unscientific, but I have not yet determined just how much should be added. I have repeated that dose as frequently as every hour for three doses. Usually the dose given will cause the patient to sleep three or three and one-half hours. Then she begins to be restless and at the first sign of restlessness the paraldehyde is repeated. In all except cases of very rapid labor, amnesia is complete. It seems to me that paraldehyde is an agent that can be given with safety. It causes the least excitement of all the drugs I have used and is easy of admin-

istration. I administer the drug in 4 cc. of physiologic solution of sodium chloride instead of in oil.

DR R. A. BARTHOLOMEW, Atlanta, Ga. Dr. Rosenfield's figures indicate clearly what can be accomplished with hospitzalized cases, both in shortening the duration of labor and in obtaining practically complete amnesia throughout the entire duration of labor. However, an average duration of labor of eight to nine hours in nulliparas indicates that the second stage of labor has been very much shortened or practically eliminated by the use of forceps. Our object in avoiding the routine use of forceps was to demonstrate to those in general practice that this method is applicable to deliveries in the home and will not increase the need for forceps delivery. We would advise those trying this method for the first time to administer it first to multiparas, since the duration of labor in this class of patients comes well within the duration of amnesia obtained with paraldehyde. It is also important to develop one's ability to judge the progress of labor by rectal rather than by vaginal examinations, since the former may be made more conveniently, quickly and without risk. From the standpoint of expense, the cost of the drugs used in this method is extremely low. Furthermore, the wide margin of safety is an important advantage. This was impressed on us recently by the accidental administration of 8 ounces (236 cc.) of paraldehyde instead of 8 drachms (30 cc.) to a male patient in the genito-urinary department of Grady Hospital. When he was sent to the operating room over one hour later he was observed to show a much greater relaxation than usual and the error was discovered. The oil and paraldehyde were washed out as thoroughly as possible but not until he had retained the dose about one and a half hours. He slept nineteen hours and made a good recovery. Hence we may say that even an excessive dose of paraldehyde seems to have no harmful effect.

THE BEARING OF CERTAIN PHYSIOLOGIC FACTS ON GASTRO-INTESTINAL SURGERY

J. SHELTON HORSLEY, M.D.

RICHMOND, VA.

William Beaumont¹ in 1833 made the first definite note on peristalsis of the stomach. His observations and experiments on Alexis St. Martin began in 1825. Beaumont had been treating this patient, who had a gastric fistula following a wound from a shotgun, for nearly three years before it occurred to him to use St. Martin as a laboratory animal and observe what occurred in the stomach during digestion. In the eight years between 1825 and 1833 he made 238 experiments. Among other things he noted that the time required for disposal by the stomach of a moderate meal is from three to three and a half hours. He showed that the agent of digestion in the stomach is the gastric juice, which acts as a solvent and contains "free muriatic acid and some other chemical principle." The other chemical principle was demonstrated a few years later by Eberle to be a specific gastric ferment called by Schwann "pepsin." He stated that gastric juice checks the process of putrefaction and that motions of the stomach produce a constant churning of its contents in two directions, transversely and longitudinally.

The introduction of roentgen rays aided greatly in the study of peristalsis. Cannon² and his associates made careful roentgenologic observations of the peristalsis of

² Cannon, W. B. Peristalsis, Segmentation and the Mysterious Reflex. *Am. J. Physiol.* 30: 114-128, 1912.

the stomach and bowel. It was noted that peristalsis began about the middle of the body of the stomach and proceeded toward the pylorus. To Cannon's observations many roentgenologists and physiologists have added interesting data. Gregory Cole³ of New York has described the cycles of gastric peristalsis. Alvarez,⁴ whose work was confirmed by Klein⁵ and others, has shown that active gastric peristalsis, which as fluoroscopically observed begins about the middle of the body of the stomach, really starts as ripples along the lesser curvature near the cardiac orifice and proceeds with increasing vigor until the middle of the body of the stomach is reached, where the waves can for the first time be observed roentgenologically. To the left of this point the contractions are largely tonic, so that the cardiac end of the stomach shoves food into the actively churning right portion of the stomach by continuous mild pressure, much as an elastic hopper would do.

The larger portion of the stomach is physiologically "silent" as to symptoms. All the greater curvature except a short portion near the pyloric end, where a lesion would produce obstruction, and much of both walls of the stomach, particularly in the cardiac portion, give no symptom of a lesion unless there is bleeding or perforation, or unless the growth is large enough to produce mechanical obstruction. In the physiologically active part of the stomach along the lesser curvature or at the pyloric end where mechanical obstruction may readily occur, lesions cause derangement of peristalsis and produce symptoms such as pain, regurgitation, waterbrash, heartburn, nausea or vomiting. About 80 per cent of all gastric symptoms are from trouble with the motor apparatus which includes not only the interference along the lesser curvature but mechanical obstruction at the narrow pyloric end.

REGURGITATION OF DUODENAL CONTENTS

Within recent years it has been demonstrated that at the end of normal gastric digestion, when the stomach has emptied its contents and strongly acid gastric juice has accumulated in the stomach, the pylorus opens and a reflux of the duodenal contents occurs. This reduces the acidity of the gastric juice.

A prolonged pyloric spasm or a mechanical obstruction, which prevents regurgitation of the alkaline duodenal contents, predisposes toward an increased tone of the stomach by retaining highly acid gastric contents and thus favors ulcer formation. Types of food that tend to irritate the gastric mucosa, reflex stimulation from some lesion in the abdomen, nervous impulses from worry, an imbalance between the vagus and the sympathetic system, particularly when the stimulating impulses dominate, all promote pylorospasm, increased muscle tone of the stomach, increased acidity of the gastric juice, and increased vascularity. The treatment of the patient for this condition is often more important than the treatment of the local gastric symptoms. When, however, there is an organic lesion that will not permit the reflux of the alkaline duodenal contents into the stomach, some surgical procedure may be indicated.

Before the establishment of the physiologic fact that duodenal contents normally regurgitate at the end of the

digestion of a meal, the presence of bile in the stomach was looked on with disfavor. The chief alkaline constituent of the duodenal contents is not the bile, whose color gives it prominence, but the strongly alkaline pancreatic juice, and the presence of duodenal contents in the stomach at the end of normal gastric digestion is probably a protective measure against the excessive acidity of the gastric juice that follows the emptying of food from the stomach when the acid of the gastric juice has no such buffer as the food.

PYLOROPLASTY AND GASTRO-ENTEROSTOMY

In functional pylorospasm, medical measures are usually sufficient. If not, the operation of Walter Hughson⁶—resection of the gastric branches of the vagus nerves—may be indicated. If there is in the duodenum near the pylorus a well limited small peptic ulcer, without surrounding adhesions or inflammation, an ulcer which has resisted medical measures, a pyloroplasty usually gives excellent results. If the lesion is extensive, if adhesions are abundant, if there is much scar tissue, and particularly if there is duodenitis, pyloroplasty is contraindicated, and gastro-enterostomy under these conditions is a satisfactory procedure in the majority of cases.

It was formerly rather popular to decry gastro-enterostomy as an unphysiologic and therefore unjustified operation, and one of the chief objections was that it admitted bile and duodenal contents to the stomach. But the knowledge that this is a normal procedure in gastric digestion and secures the desirable reduction of the acid values of the gastric juice justifies gastro-enterostomy, for it seems to restore this physiologic function of regurgitation of the duodenal contents which has been prevented by pyloric obstruction.

Mann and his associates⁷ have convincingly shown that in dogs the so-called surgical drainage of the duodenum almost always results in peptic ulcer. In this procedure the jejunum some distance below the duodenum is divided and the duodenum is severed at the pylorus and its end closed. The distal end of the jejunum is sutured to the pylorus and the proximal (oral) end is implanted into the small bowel lower down, thus depriving the portion of the jejunum attached to the stomach of the alkaline contents of the duodenum. These experiments show the fallacy of the Roux or Y gastro-enterostomy, which is practically surgical duodenal drainage and deprives the bowel attached to the stomach of the protective alkalinity of the duodenal contents. Entero-anastomosis between long loops of jejunum, as after anterior gastro-enterostomy or some types of partial gastrectomy, is for the same reason objectionable but doubtless diverts from the segment of bowel attached to the stomach only a portion of the alkaline duodenal contents instead of all of it, as in the Y technic.

CHOLECYSTOGASTROSTOMY FOR THE CURE OF PEPTIC ULCER

The advocacy of a cholecystogastrostomy for the cure of peptic ulcer seems to be founded on three physiologic fallacies, any one of which is fatal. It has been assumed that the union of the gallbladder to the stomach would provide a constant natural alkaline fluid, which

would tend to lower the gastric acidity and so promote the healing of the ulcer. The fallacies follow: 1 Bile has a very low alkaline value and is often neutral. The alkalinity of the duodenal contents resides chiefly in the pancreatic juice, which is highly alkaline, but pancreatic juice does not normally enter the gallbladder. The biliary coloring of the duodenal contents gives the superficial impression that bile is the most important constituent, when it is probably the least important. 2 If there is no obstruction to the common duct, the discharge of bile from a cholecystostomy is comparatively slight. Surgeons have noted that, after the inflammation has cleared up and if the common duct is open, but little bile comes from a cholecystostomy. It seems probable that but little bile would escape from a normal gallbladder connected with the stomach unless the common duct should be obstructed or ligated—a remedy worse than the disease. So even if the bile were strongly alkaline, which it is not, but little of it would be delivered into the stomach. 3 The third fallacy is that no account is taken of the effect of the gastric juice on the gallbladder. In cases in which there is obstruction of the common duct from cancer of the head of the pancreas, the acid values in the gastric juice are usually low and cholecystogastrostomy as a procedure to relieve jaundice in these cases doubtless has a definite place. But it must be recalled that in a peptic ulcer the acid values of the gastric juice are frequently quite high, and if bile goes through a cholecystogastrostomy into the stomach the acid gastric juice with its irritating effect on a mucosa unaccustomed to acid likewise goes into the gallbladder. It has also been shown experimentally that a cholecystogastrostomy is quite constantly followed by an ascending infection and an eventual hepatitis.

V-SHAPED AND MIDGASTRIC RESECTION

If a large V-shaped section of the stomach of a dog is removed with the base on the greater curvature and a small channel is left along the lesser curvature there is but little interference with gastric function. If, however, a V-shaped section is taken from the lesser curvature, the gastric motor function is upset.^{5b} This should indicate that whenever possible in a local operation on the stomach the structures along the lesser curvature should be respected and preserved. Not only is a V-shaped resection of the lesser curvature of the stomach unsatisfactory as to restoration of function, but a midgastric resection usually gives bad functional results. There is a tendency to constriction and hour-glass deformity, and the interruption of the impulses to the pyloric portion of the stomach not infrequently causes motor disturbance.

PARTIAL GASTRECTOMY

In gastric ulcers that do not readily yield to medical treatment and, of course, in cancer of the stomach a partial gastrectomy is indicated. With ulcers in somewhat inaccessible regions, as in the cardiac portion of the stomach, a local excision may be the best therapeutic procedure, but this should be accompanied either by a pyloroplasty, if the tissues of the pylorus and duodenum are normal, or by a gastro-enterostomy if they are diseased. In this way the healing of the gastric wound is promoted by decreasing the acidity of the gastric juice in providing a ready reflux of the duodenal contents and by lessening the work of the stomach by making a neasy exit which reduces the burden on its muscular apparatus. When, however, the lesion is in the body

or in the pyloric portion of the stomach, a partial gastrectomy is appropriate.

Partial gastrectomy is divided into two general classes: Billroth I, in which the stump of the stomach is sutured to the duodenum, and Billroth II, in which the stump of the stomach is united to the jejunum and the end of the duodenum is closed.

The lesser curvature of the stomach, where the initiation of motor function resides, should be respected. If in the Billroth I operation it is aimed with the upper border of the duodenum, according to nature, and the duodenum is flared open, the lower portion of the gastric stump can be readily closed, sometimes even an end-to-end union may be made. Then motor function is preserved as nearly in the natural manner as possible.⁸

Physiologists have shown that the sensitiveness of the intestinal mucosa to the acid of the gastric juice increases from the duodenum down. If the duodenal mucosa were as sensitive to the acid gastric juice as the mucosa in the lower part of the ileum, every one would probably have duodenal ulcers. It is because of this relative resistance that duodenal ulcer is not more common. When a segment of the jejunum is united to the stump of the stomach in which the acid values of the gastric juice are high, an excellent situation for jejunal ulcer is at once created. In cancer of the pyloric end of the stomach, when the acid of the gastric juice is low or even absent, it may be anticipated that if cancer does not recur the gastric juice will resume some of its acidity. If this happens, the patient would be in a more fortunate position to have the stomach contents empty on to the resistant duodenal mucosa than on the jejunal mucosa. If the gastric resection leaves much of the stomach affected by peristalsis, the stoma should always include the lesser curvature with its active part in peristalsis. But if the actively peristaltic portion of the stomach has been removed, there is no particular indication for having the opening of the gastric stoma high up. When the remaining stump of the stomach is controlled from a motor standpoint solely by tonic contractions, as from a rubber bag, the stoma may just as well be at the lowest point, for here gravity assists in emptying the stomach, but gravity plays but little part in the peristaltic part of the stomach.

In some cases the stump of the stomach cannot be brought to the duodenum, and here a form of the Billroth II operation must be employed. The Hofmeister modification of the Billroth II operation, in which the stoma is made along the lower border of the stomach and the upper part of the gastric stump is closed, is an excellent procedure. It lessens the length of the jejunal loop necessary when a Polya operation is done and gives ample egress for the stomach contents without an unnecessarily large opening that may interfere with gastric digestion. Lahey⁹ suggests freeing the oral loop of the jejunum in the Polya operation so that it does not lie below the transverse mesocolon. This should avoid the necessity of an entero-anastomosis, which sometimes arises in these cases.

When a partial gastrectomy is to be done for cancer, hydrochloric acid should be freely given for several days before operation for its antiseptic value—a function of the acid gastric juice first noted by Beaumont.

PERSISTENTLY RECURRING PEPTIC ULCERS

Unfortunately, there are a few cases of tendency toward peptic ulcer in which no form of therapy, either medical or surgical, seems effective. Harvey Cushing¹⁰ has renewed the interest in Rokitsansky's theory of the neurogenic origin of peptic ulcer, asserting that an imbalance between the vagal and the sympathetic impulses (usually an excess of vagal stimuli) is responsible for many peptic ulcers. Crile's¹¹ interesting work on the suprarenals is also suggestive. Certain it is that, at least in this small percentage of cases of persistently recurring peptic ulcer, some causes outside of the gastro-intestinal tract must be responsible. A discussion of this relationship, however, will carry us too far afield. Balfour¹² has proposed physiologic rest for the stomach by feeding through a jejunostomy for a period of a year or more, and in some peptic ulcers this has produced good results. But when gastric feeding is resumed in such cases the ulcers often recur. Whether complete section of the vagus nerves just below the diaphragm would add to the effectiveness of the treatment it is at present impossible to say, though it is suggestive of beneficial results. In some of these cases a total gastrectomy may be considered, though the eventual results of such a procedure as regards anemia have not been fully determined. There are a few cases in which anemia supervenes and others in which it does not seem to occur.

OPERATIONS ON THE SMALL INTESTINE

In the small intestine, the chief physiologic facts that bear on surgical operations have to do with the active, sensitive and rather delicate peristalsis of the upper part of the small intestine as compared with the lower part, and with the scanty bacterial content of the upper part of the small intestine caused by the bactericidal action of the hydrochloric acid of the gastric juice whereas in the lower ileum bacteria are abundant. Dragstedt¹³ has shown that in the upper part of the small intestine of a dog obstruction will result from an amount of pressure that in the lower ileum will not produce obstruction. The scantiness of bacteria in the upper small intestine together with the more abundant blood supply favors the healing of wounds in this region. An open technic for resection, then, without any unnecessary soiling, preferably an end-to-end union providing a wide lumen and a small diaphragm, is indicated in the upper small intestine. One row of continuous sutures with a few interrupted sutures for reinforcement seems to be better than multiple layers, which turn in much tissue and thus may cause obstruction in this sensitive bowel. The more accurate suturing of the inner coats of the bowel is usually preferable to their blind closure by the so-called aseptic technic.

In the lower small intestine, with the fat encroaching on the sides of the bowel, as has been well demonstrated by Monks,¹⁴ an end-to-end union is less desirable. The dangerous triangular space with its potentialities for infection and poor healing where the mesentery separates to surround the bowel is larger, and suturing the intestine along the fat mesenteric border becomes less

safe than in the jejunum. Here peristalsis is not so active, though it is rather strong. If the lumen is small and the fat abundant, it would seem a better procedure to close the ends as aseptically as possible, the cautery and basting stitch being used, and make a lateral anastomosis. Care should be taken to leave no pocket in the oral end of the bowel, because food accumulates in it with the peristaltic urge, and in experimental animals perforation may occur.

OPERATIONS ON THE COLON

The colon is divided by its physiologic function into right and left sides. The right side is the chief means for the absorption of water and salts, the left side is mainly for storage. If excision of the right colon is indicated, a preliminary end-to-side anastomosis of the ileum to the transverse colon should be done, with removal of the right colon at the same or at a subsequent stage. When the transverse or left colon must be resected, complete preliminary rest for one or more weeks should be obtained for this portion of the bowel by an enterostomy in the cecum and first part of the ascending colon, which will divert the entire fecal current from the left colon. This not only provides physiologic rest but reduces the bacterial content of the left colon to about the same as that of the jejunum and so increases the safety of its resection. This safety is still further augmented by the administration of an appropriate intraperitoneal vaccine. When the site of the resection has healed, the colostomy is closed.

CONCLUSION

Some knowledge of the physiologic functions of the gastro-intestinal tract—of its motion, its secretions and excretions, its contents, its power of absorption and its relationship to other organs—is essential to satisfactory surgery of the stomach and intestine.

617 West Grace Street

ABSTRACT OF DISCUSSION

DR. GEORGE W. CRILE, Cleveland. As Dr. Horsley has said, it is oftentimes more important to treat the patient than the ulcer. The ulcer after all is an end result and a symptom, not a disease primarily. That is well established by the fact that the people who are the most intelligent, the most active, who have the greatest responsibilities, worries and anxieties, are those who are most prone to the development of peptic ulcers. In certain patients, on many of whom operations for peptic ulcer had been performed before I saw them, in some cases as many as six, I have resorted to a procedure that tends to interfere with the sphincterismus at the pylorus and also with the mechanism by which the excited man, the high tempered man and the civilized man interferes with his own processes, the suprarenal-sympathetic system. I have divided the nerves leading from the suprarenal glands, and it has been interesting to note that, as soon as the suprarenal glands are denervated, the patient is relieved. Among forty patients in whom this operation was performed and who had previous operations and recurrences of the ulcer, four were surgeons. As soon as this operation is performed the sphincterismus disappears, the abnormal motility disappears, as shown by the fluoroscopic examination and of course by the immediate relief experienced by the patient. Occasionally there will be some remissions, but these are unimportant as they are rather easily controlled. I cannot state as yet how permanent these results will be. In the oldest case, operation was performed nearly five years ago. If the results prove to be permanent, I should think one would be justified in performing first a left suprarenal denervation and then a resection of the ulcer. If after three or four months the patient is relieved but not cured, the other suprarenal can be denervated.

JAUNDICE

A REVIEW OF SOME EXPERIMENTAL INVESTIGATIONS

FRANK C MANN, MD

AND

JESSE L BOLLMAN, MD

ROCHESTER, MINN

Jaundice appears to be one of the first clinical signs to be mentioned in the history of medicine as characteristic of disease. Continuous investigation has accumulated a mass of information relative to both clinical and experimentally produced jaundice. It is not possible adequately to review all of this material at one time, either from a clinical or from an experimental standpoint. We will limit ourselves to reviewing certain experimental investigations which have added facts of interest to the knowledge of jaundice. Because our interest is largely in the field of hepatic physiology and pathology, our investigations have been limited to those phases of jaundice in which the hepatic factor appears to be paramount. The physiologic changes incident to obstructive jaundice have been reviewed by Ivy,¹ and the extrahepatic functions of bile by Schmidt,² so that these phases of the subject need not be presented here.

Jaundice may be produced in animals by many different methods, all of which have one common feature, that is, production within the animal of more bile pigment than is eliminated by the liver at the same time. As far as we are aware, true hemolytic icterus, similar to the condition as seen in the human being, has not been produced experimentally in animals, although jaundice may be produced by injections of hemolyzed blood or by injections of various hemolytic agents. Injection of these substances gives rise to excretion of hemoglobin in the bile and causes retention of bile pigment. The bilirubin that accumulates in the blood after these procedures gives a direct van den Bergh reaction. The jaundice that follows complete removal of the liver, with or without subsequent injections of hemoglobin, may be said to be a hemolytic type of icterus, since only the indirect van den Bergh reaction is obtained. Jaundice that might be termed hepatic may be produced by obstruction of the common bile duct or by impairment of the secretion of bile by injury to the liver. The latter may be produced by administration of chloroform, phosphorus, carbon tetrachloride, and other hepatic toxins. The effects of the jaundice on the animals will vary somewhat, depending on the method used to produce the jaundice and may also be complicated by the effects of the method itself.

Regardless of the method employed to produce the jaundice, the results noted may be due to three factors always present in the icteric animal: the effect on the body cells of retention of bile in the blood and tissue fluids, the effect of absence of, or alteration of, the bile in the intestinal tract, and the effect of the injury to the liver which accompanies jaundice. As yet, the effects of these three factors cannot be differentiated, except in regard to the effects of the absence of bile from the intestines which has been determined by many excellent studies on bile fistula animals. Complete loss

of bile is compatible with life for an indefinite period if adequate care and a suitable diet are maintained. There are many changes in digestion and absorption in these animals, such as Greaves and Schmidt³ have shown in the failure of absorption of vitamin D, but these changes can be controlled by proper dietary regimens. Queen, Hawkins and Whipple⁴ have added the important observation that modifications which are ineffective on the normal animal may produce marked changes and death of animals with complete biliary fistula. Thus, a short period of time after splenectomy performed on a bile fistula dog there develop an overproduction of bile pigment and marked anemia, which are progressive until death. Some similar agency may be responsible for the fact that dogs with complete obstructive jaundice gradually decline and in spite of all forms of dietary treatment usually fail to survive more than a year.

Some of the nutritional disturbances found in jaundiced animals are associated with loss of normal bile from the intestine, but other disturbances, such as loss of appetite, appear to be due to the effects of the retained bile. The anemia and diminution of plasma protein that occur in the icteric animal may be in part due to dietary and absorptive factors, but it is probable that associated hepatic injury also plays an important part. Smith and Whipple⁵ have demonstrated that hepatic injury not only decreases the amount of hemoglobin regenerated while the animal is on standard diets but also that the liver plays a major part in the formation of the plasma proteins. We have found a marked tendency to the development of peptic ulcers on the part of jaundiced animals. These ulcers are usually duodenal and may develop after a few days of jaundice or may not develop for many months, but eventually perforation of an ulcer is the chief cause of death of our animals with complete obstructive jaundice. Because we have not been able to demonstrate any changes in the acidity of the gastric or duodenal content of these animals in which ulcer develops, we are inclined to ascribe the formation of the ulcers to some general effect of the jaundice, in which the resistance of the gastric and duodenal mucosa to formation of ulcer is definitely reduced.

Certain other changes in the jaundiced animal should be noted, which are probably associated with changes in the liver and are only in part specific for jaundice. In view of the associated anemia and decreased protein content of the plasma, it might appear that large amounts of meat should be added to the diet. That the reverse is true is readily seen when the survival time of jaundiced dogs on a meat diet is compared with that of dogs fed mainly carbohydrate and the proteins of milk and eggs. After about three months of complete obstruction of the biliary outflow, few animals will survive a diet of meat for more than a week but will live for several months on a diet of milk and syrup. There is also some relationship existing between the extractions of meat and the ascites that often occurs in the

terminal stages of obstructive jaundice. If sufficient injury has occurred to the liver (usually about three months of complete obstructive jaundice), feeding of meat, or the administration of beef extract, will produce rapid formation of ascites in animals that were free of ascites when maintained on a diet almost free of these substances, the animals again become free of ascites in a few days after the resumption of the original diet. There are probably other factors involved in the formation of ascites in these animals, as, for example, the reduction of the protein content of the plasma, and altered absorption from the intestine, but the effect of the extractives of meat is most striking when one observes the development of more than 3 liters of ascitic fluid in six hours in an animal weighing 15 Kg following oral administration of 15 Gm of meat extract.

Accumulation of bile pigment in the tissues may not be the most important feature of jaundice, but it is certainly the most noticeable. Because of its ease of detection and a fairly satisfactory method of quantitation, more is known about bilirubin than about the other constituents of the bile. Bile pigment continues to be formed in animals after complete removal of the liver, and there can be no doubt that hemoglobin is the material from which it is derived. Injections of hemoglobin increase the formation of bilirubin, as has been demonstrated in the bile fistula animals, jaundiced animals and dehepatized animals. Simultaneous determinations of the bilirubin content of the arterial blood flowing to various organs and tissues, and of the venous blood returning from the same organs and tissues, have demonstrated formation of bile pigment in the spleen, bone marrow and liver. Other tissues investigated do not appear to add bilirubin to the blood. It appears that the bilirubin is formed in the cells of the reticulo-endothelial system, which in mammals is greatest in the bone marrow, spleen and liver, and there is evidence to indicate that the bone marrow is normally the main site of formation of bilirubin.

It has not been proved that the hepatic cell forms bilirubin. The main evidence presented to date that the hepatic cell makes bilirubin is that the jaundice produced by certain substances, notably toluylenediamine, is prevented by removal of the liver.⁶ Toluylenediamine produces both increase in the formation of bilirubin and retardation of its excretion together with demonstrable injury to some of the hepatic cells. In order to explain the jaundice produced by this substance, on the basis that the retained bilirubin is formed by the hepatic cells, it is necessary to postulate that toluylenediamine injures the hepatic cells in such a manner that they form more bilirubin than normal and excrete less than normal. This consideration must remain as a possibility until the mechanism of the jaundice caused by toluylenediamine is conclusively determined, although it appears rather unique that injury to a cell should cause it to increase its activity in one respect and decrease it in another.

The liver may be considered as an excretory organ for bile pigment, since not only is the major amount of bilirubin formed outside the liver but accumulation of this substance in the blood and tissues occurs when hepatic excretion is impaired or prevented. Removal of the liver, or ligation of the biliary ducts, prevents excretion of bile into the intestine and bile pigment

formed outside the liver appears in the blood, body tissues and urine. Acute lesions of the liver may also produce jaundice such as follows: administration of chloroform, phosphorus, carbon tetrachloride or tetrachlorethane. We also see temporary jaundice following removal of a large amount of hepatic tissue. We have recently observed jaundice following continuous injection of dextrose for many hours at the maximal rate of tolerance. The glycogen content of the liver is increased up to 20 per cent of its weight, but the carbohydrate functions of the liver do not appear altered. Bile pigment, however, is retained in the blood and is excreted in the urine. The jaundice produced by hepatic poisons appears to be due in part to hepatic injury and in part to excessive formation of bilirubin, which cannot all be eliminated by the injured liver. The jaundice that occurs after partial removal of the liver and injection of large amounts of dextrose appears to be due to the fact that these procedures cause the hepatic cells to swell and to obstruct the bile canaliculi.

The van den Bergh reaction for serum bilirubin is indirect in animals that have become jaundiced following complete removal of the liver. The amount of bile pigment that accumulates in the blood for the first twenty-four hours after removal of the liver is comparable in amount to that which is found after an equal interval of time following ligation of the common bile duct and extirpation of the gallbladder. In the latter case the bilirubin of the blood gives a direct van den Bergh reaction. Removal of the liver when obstructive jaundice is present produces serum bilirubin with a true biphasic reaction obtained by the van den Bergh method. If the liver is removed several hours after ligation of the common bile duct and removal of the gallbladder, at a time when a definite direct van den Bergh reaction is present in the serum, the amount of bilirubin reacting directly will be subsequently unchanged. Additional bilirubin will accumulate in the blood after removal of the liver so that the total amount of bile pigment in the blood will progressively increase at the same rate that it was increasing following ligation of the common bile duct, but the bilirubin that is added to the blood after removal of the liver gives only the indirect reaction. In any other type of jaundice that we have produced experimentally there has been more or less involvement of the liver, and the direct van den Bergh reaction for bilirubin in the blood has been observed.

No important function has been ascribed to bilirubin except that of an excretory product derived from the breakdown of hemoglobin in the body. Hawkins, Sribbshaj, Robschert-Robbins and Whipple⁷ found that anemic dogs formed new hemoglobin from the entire amount of foreign hemoglobin administered but at the same time formed additional bilirubin equivalent to the entire amount of hemoglobin given. These observations indicate that new hemoglobin must be synthesized and that the bilirubin portion of the hemoglobin molecule cannot be utilized in the formation of new hemoglobin, although other portions of the hemoglobin molecule may be incorporated in new hemoglobin.

The bilirubin excreted in the bile is not reabsorbed as such but is acted on by bacteria and perhaps some intestinal enzymes to form urobilinogen and urobilin,

which may be absorbed into the portal system. Most of the absorbed urobilin is absorbed by the liver and excreted again into the intestine. No urobilin is formed if bilirubin is not present in the intestine except in some instances of cholangitis in which the urobilin is formed in the infected bile ducts. McMaster and Elman⁸ found that injury to the liver prevented urobilin being excreted in the bile, and the excess pigment was excreted in the urine. Excessive excretion of bilirubin in the intestine such as follows excessive destruction of blood, increased the amount of urobilin formed, beyond the capacity of the liver to excrete it immediately, and some of the urobilin was excreted in the urine. Apparently the liver is extremely sensitive in regard to excretion of urobilin, since it appears in the urine in fevers and in many nonspecific infections that do not appear to involve the liver.

Bile salts, like bile pigment, are intimately connected with any consideration of jaundice. Additional interest is afforded by the fact that bile salts have some toxic action on the tissues. Osterhout⁹ found that the presence of bile salts decreases the permeability factor of tissues. Horrall and Carlson¹⁰ observed that the toxicity of bile depended on the rate of administration rather than on the total amount administered, and Still¹¹ concluded that the cholate radical was mainly responsible for the toxicity of bile. Sterner, Bartle and Lyon¹² have reviewed the recent literature on metabolism of bile salts. This may be briefly summarized as follows. The bile salts have one definite function in emulsifying and aiding in the digestion of fats in the intestine, and bile salts stimulate the liver to cause greater amounts of bile to be formed and secreted. Smith and Whipple⁵ have conducted a large series of studies on the excretion of bile salts by biliary fistula dogs under a number of different conditions. They found that standard diets of salmon bread produced a constant daily excretion of about 100 mg of taurocholic acid for each kilogram of body weight, whereas fasting or feeding with sugar reduced this figure to 20 or 40 mg. Feeding of liver, kidney or beef muscle produced from 200 to 300 mg of taurocholic acid for each kilogram of body weight in twenty-four hours. Casein produced from 125 to 190 mg of taurocholic acid, ovalbumin produced 50, and whole beef blood increased the excretion of bile salts, but the erythrocytes alone caused a slight decrease. Amino-acids and other substances that possess chemical structures found in taurocholic acid cause increased formation of bile acid if added to certain diets but may be without effect when added to other diets, therefore it would appear that certain amino-acid complexes were necessary for formation of bile salts but that excess of these complexes may be without further effect. Bile salts administered by vein or by mouth are quantita-

tively excreted in the bile. There are many indications that the liver is probably responsible for elaboration of bile salts, although the evidence to date is not conclusive. Mild hepatic injury, such as is produced by small amounts of chloroform or by an Eck fistula, may greatly reduce the amount of bile salts formed, but the amount of hepatic injury that may be observed microscopically does not always parallel the reduction of formation of bile salts, since phosphorus poisoning may produce extensive hepatic injury, with little reduction in the excretion of bile salts.

Our studies¹³ indicate that the normal animal is able to destroy large amounts of glycocholates or taurocholates following administration of these substances by vein or by mouth. After ligation of the common bile duct, more of the injected bile salts appear in the urine but a considerable portion of the bile salts are destroyed. If the liver is completely removed, all of the bile salts administered appear in the urine after a few hours, so that it would appear that the liver plays a prominent part in the destruction of bile acids. Additional evidence of the formation of bile salts in the liver is found in the fact that no bile salts can be detected in the blood or urine after removal of the liver, although bilirubinemia develops and bile pigment is present in the urine, and small amounts of administered bile salts may be detected.

With complete obstruction of the biliary outflow, the amount of bile salts excreted in the urine is only about half of that found in normal animals with biliary fistulas. Injury to the liver by chloroform, carbon tetrachloride or toluenylenediamine further reduces the amount of bile salts in the urine and blood. The terminal decrease in excretion of bile salts in continued obstructive jaundice does not occur until considerable secondary hepatic injury is demonstrable. At this time the ability of the liver to destroy bile salts may not be altered, so that the decrease in excretion of bile salts is obviously due to decreased formation of bile salts. Jaundice produced by hepatic toxins such as chloroform, phosphorus, carbon tetrachloride or toluenylenediamine in otherwise normal animals gives rise to excretion of bile salts in the urine, and bile salts are found in the blood. As these animals recover, the bile salts disappear from the blood and urine, but bile pigment may still be present in large amounts. Additional hepatic injury, by repeated administration of the toxic agent, may also cause disappearance of the bile salts from the blood and urine. With recovery from hepatic lesions, bile salts are excreted in the bile, and hepatic activity prevents accumulation of these substances in the blood. With further injury, the liver is unable to elaborate bile salts so that they also disappear from the blood.

SUMMARY

Jaundice may be produced experimentally by methods that involve the liver. Complete removal of the liver produces jaundice that might be termed hemolytic, and the bilirubin of the blood is found to respond "indirectly" to the van den Bergh reaction. Other forms of jaundice produced by occlusion of the bile ducts or by hepatic injury increase the bilirubin content of the blood, which is found to give a "direct" van den Bergh reaction.

Experimentally produced jaundice, continued for some time, produces certain typical effects on the animal,

owing to the absence of or alteration of bile in the intestine, the presence of bile components in the blood and tissues, and the associated impairment of the liver. Survival of these jaundiced animals is limited by several factors. Nutritional disturbances, in which decreased tolerance to meat is a prominent feature, are important. There appears to be a definite tendency to the occurrence of peptic ulcer. Anemia and a decrease in the proteins of the plasma are usually found to be associated with injury to the liver. Ascites may be formed under conditions in which it does not occur in normal animals.

Formation of bile salts is somewhat reduced in icteric animals but continues to be formed in considerable amounts. Subsequent injury to the liver of the jaundiced animal may completely prevent formation of bile salts, so that they are no longer found in the blood or urine.

SLIGHT AND LATENT JAUNDICE

THE SIGNIFICANCE OF ELEVATED CONCENTRATIONS OF BILIRUBIN GIVING AN INDIRECT VAN DEN BERGH REACTION

HENDRIK M. ROZENDAAL, M.D.

Fellow in Medicine the Mayo Foundation

MAADRE W. COMFORT, M.D.

AND

ALBERT M. SNELL, M.D.

ROCHESTER, MINN.

For years we have puzzled over the meaning of a slight increase in the value of serum bilirubin, with or without slight jaundice barely detectable either by the patient or by the trained physician. Naturally we have suspected that in at least some of these cases the liver has suffered an injury leading to dysfunction, but we could not be sure. In the hope of throwing light on the problem, we have analyzed the data in all such cases encountered at the Mayo Clinic from 1930 to 1931.

It will be remembered that in most laboratories today the concentration of serum bilirubin is classified and measured by van den Bergh's technic. At the clinic Lepehne's ring test is first applied to determine the type of bilirubin reaction. If, after the diazo-reagent has been added, a purple color appears within one minute, the reaction is said to be "direct," if the appearance is delayed from two to five minutes, it is called "delayed-direct," and if it appears after five minutes it is called "indirect." Most investigators believe that the direct reaction is given by reabsorbed bilirubin that has passed through hepatic cells normal or diseased, the bilirubin that gives an indirect reaction is supposed not to have passed through the hepatic cells. As a corollary of this, direct reactions are supposed to indicate injury to the liver or obstruction of the ducts, an indirect reaction is found in blood from all normal persons and from patients with hemolytic disease. The delayed direct reaction probably has the same significance as has the direct reaction. In this study we have disregarded all cases in which reactions were direct, because we know that a direct reaction means something is wrong with the liver or ducts. We were not so sure about the significance of the indirect reactions, hence, this analysis.

The concentration of serum bilirubin also is measured quantitatively. Using Thannhauser and Andersen's¹ modification of the van den Bergh technic, we have found that the serum of most normal persons contains less than 1.5 mg. per hundred cubic centimeters of bilirubin. In order to be safely above this usual range of concentration, we have picked out for the purpose of this study 214 consecutive cases in which the amount was 2 mg. or more per hundred cubic centimeters.

Before continuing, it might be helpful to remember that nowadays cases of jaundice are divided into three groups: (1) cases of extrahepatic jaundice, in which obstruction to the bile ducts is produced in any way, (2) cases of intrahepatic jaundice, in which the disease is in the hepatic cells, and (3) cases of hemolytic jaundice, in which the liver and bile ducts are assumed to be normal and the bilirubinemia to be due to excessive destruction of erythrocytes.

In this study not only did we hope to throw light on the meaning of increased concentrations of bilirubin with an indirect reaction but also we thought we might learn something about those many patients who claim to be bilious, liverish or toxic but in the examination of whom the usual tests of hepatic function fail to show any sign of disease.

MATERIAL

We found that the records of the 214 cases could be divided into two groups. In the first group were patients who had, as well as patients who had not, disease of the liver and gallbladder. Hemolytic disease was excluded by appropriate laboratory and clinical data. In table 1 are summarized the diagnoses made in cases in which hemolytic disease was absent, and also it is indicated whether or not visible jaundice was present. Chrometzka,² Schiff,³ Hughes⁴ and Perkin,⁵ among others, previously have noted cases in which concentrations of bilirubin were increased, the reaction was indirect and the patients had disease of the liver or gallbladder.

In the second group, some type of hemolytic disease was present in each case (table 2). Whereas most of the important types of hemolytic diseases are included in this series of cases, there are others, such as purpura, poisoning by potassium chlorate and by snake bite, and sickle-cell anemia, which may be mentioned for the sake of completeness. Extravasation of blood in the presence of pulmonary infarcts and tubal pregnancy likewise produce excessive hemolysis and bilirubinemia.

The greatest concentration of serum bilirubin encountered in this series was less than 7 mg. per hundred cubic centimeters. The concentration was 3 mg. per hundred cubic centimeters or less in approximately 75 per cent of the cases. It is interesting to note that visible jaundice occasionally is present when the concentration of serum bilirubin is less than 3 mg. per hundred cubic centimeters, on the other hand, it is rarely absent when the concentration is more than 3 mg. per hundred cubic centimeters.

INCREASED CONCENTRATIONS OF BILIRUBIN IN
CASES IN WHICH HEMOLYTIC DIS-
EASE WAS ABSENT

The balance between the formation of bilirubin by the reticulo-endothelial system and its excretion by the hepatic polygonal cells is well maintained in health. The balance is upset by disease, which either increases formation or retards excretion. The concentration of bilirubin is often lower than normal when the erythrocytes are deficient in hemoglobin, as in hypochromic anemia. The concentration of bilirubin increases when hemolysis is excessive, as in hemolytic disease, and when injury and dysfunction of the hepatic cell occur. Such is the modern conception of the physiologic processes relative to bilirubin.

It follows that hepatic dysfunction may well be responsible for the increased concentration of bilirubin in the cases in which hemolytic disease has been ruled out. Interestingly enough, in all cases of this series in which hemolytic disease was absent, hepatic disease or dysfunction is actually or probably present to account for the presence of an increased concentration of bilirubin. Two types of hepatic dysfunction may

be recognized (1) a constitutional type and (2) a type secondary to hepatic disease. Each type will be briefly considered.

Constitutional hepatic dysfunction was described by Gilbert and his associates⁶ as simple familial cholemia

and simple chronic icterus. In simple familial cholemia the concentration of serum bilirubin was increased, the skin had a slightly yellowish or sallow tint, the conjunctivae were not colored, the urine contained appreciable amounts of urobilin and urobilinogen, and the liver and spleen were affected very slightly, if at all. In simple chronic icterus the concentration of serum bilirubin

was increased still further, the skin and conjunctivae had a subicteric or definitely icteric tint, the urine contained considerable amounts of urobilin and urobilinogen (at times even a small quantity of bilirubin) and the spleen and liver were often, although only slightly, affected. The forty-eight cases in our series in which there was no demonstrable disease of the gallbladder or liver belong to these groups, in addition there were ten patients who had disease of the gallbladder, and two who had disease of the liver and who had jaundice long before the development of disease of the gallbladder or liver, and these should be added to make a total of at least sixty cases in which there was some type of hepatic dysfunction. In all probability the condition of the twenty-six patients who were not jaundiced, corresponded to the condition known as simple familial cholemia, and that of the thirty-four patients who were jaundiced typified the condition known as simple chronic icterus. Cases 1 and 2 illustrate the typical features of this type of dysfunction.

CASE 1—A man, aged 32, had always been aware of slight jaundice. His mother, five brothers and one sister had the same trouble but were otherwise in good health. Physical examination revealed nothing important except the icteric sclerae. Examinations of the blood disclosed cells of normal morphology, normal fragility of the erythrocytes in hypotonic salt solution, and a normal percentage of reticulated erythrocytes. Roentgenologic examination of the gallbladder revealed that it was functioning normally. The bromsulphalein test of hepatic function disclosed retention of dye graded 1. Three readings of bilirubin ranged from 2.8 to 3.4 mg per hundred cubic centimeters of serum, once the van den Bergh reaction was delayed-direct, and twice it was indirect.

In nine other cases the jaundice likewise began at birth. In four other cases, other members of the family were similarly affected.

CASE 2—A man aged 26, complained of exhaustion and slight jaundice, which had appeared about three years before we saw him. He gave no history of cramps, colic or fever. The only important finding was the slight jaundice. Anemia and abnormal fragility of the erythrocytes were absent. The readings for serum bilirubin were 3.4, 3.6 and 4.2 mg per hundred cubic centimeters, and the van den Bergh reaction was indirect. Roentgenologic examination of the gallbladder disclosed that it was functioning normally.

Two years later the patient returned, he was still weak and tired, the jaundice was unchanged. The blood picture was not that of hemolytic icterus. The reading for serum bilirubin was 4.2 mg per hundred cubic centimeters and the van den Bergh reaction was again indirect.

Fragility of the erythrocytes in hypotonic salt solution was normal.

⁶ Gilbert A and Lereboullet P. La cholemie simple familiale, Gaz hebdomadaire de med 49: 889-897 (1902). Sur la teneur en bilirubine du serum sanguin dans la cholemie simple familiale. Compt rend. Soc de biol 58: 937-940 (June 3) 1905. La cholemie simple familiale sous l'importance en pathologie. J med franc 110: 119 (March) 1910. Gilbert A, Lereboullet P and Herscher P. Les trois cholemes congenitales. Bull et mem Soc med d hop de Paris 24: 1203-1211 (Nov 15) 1909.

Two months later, during a bilious spell, the concentration of serum bilirubin was 63 mg per hundred cubic centimeters and the van den Bergh reaction was delayed-direct. The test of fragility of erythrocytes gave a normal result. Seven months after that, the condition of the patient and the results of laboratory examinations were similar to those found on his first examination. In addition, a bromsulphalein test of hepatic function failed to give evidence of any retention of dye.

In thirteen other cases the jaundice likewise began after birth. In one case, other members of the family of the patient were similarly affected. The onset never was spectacular. The jaundice was usually so slight that it is probable that in some cases it was present long before it was noticed. It is certain that a visible grade of icterus, easily recognizable, has escaped the attention of ten of the thirty-four jaundiced patients. Under these circumstances it is possible that jaundice and hepatic dysfunction, listed as beginning some years after birth, really had its onset at a very early age. It is also worth noting that, although seven patients were sure the jaundice had been absent at intervals, it showed no tendency to disappear permanently.

These examples of chronic and intermittent jaundice resemble cases of chronic hemolytic jaundice. It is significant, however, that no history of hemolytic crises with anemia, no evidence of increased destruction of blood or increased regeneration, or no constitutional variations in morphology of the erythrocytes peculiar to chronic hemolytic icterus were present. Moreover, the spleen was not palpable, in fact, all the criteria on the basis of which a diagnosis of chronic hemolytic icterus is commonly made were lacking in these cases. These fundamental differences from chronic hemolytic icterus were likewise noted in the cases in which jaundice was absent.

In spite of the fundamental differences, the constitutional jaundice in these cases is often considered to be of hemolytic origin. Weber,⁷ for one, Schliff for another, and Gänsslen, Zipperlen and Schuz⁸ interpreted such cases as being atypical examples of chronic hemolytic icterus. That such an interpretation is made is not surprising when one remembers that constitutional jaundice occurs in families the members of which also have chronic hemolytic icterus. Moreover, since it is known that spherical microcytosis may be lacking in certain cases of chronic hemolytic icterus and that normal fragility of the erythrocytes may be present at one time and abnormal fragility at another time, it is possible that in some of these cases later there may be evidence of hemolysis. The assumption, however, of a hemolytic origin for the hyperbilirubinemia in these cases is hardly justified without more evidences of excessive hemolysis.

Pende⁹ classified the hepatic dysfunction of this group of patients among forms of constitutional inadequacy, and van den Bergh¹⁰ expressed the belief that the elevated threshold for excretion of bilirubin in these cases is physiologic. Mogena,¹¹ on the other hand, has expressed his feeling that the increase is invariably pathologic. In our opinion, actual dysfunction of the

polygonal hepatic cells exists. When jaundice appears years after birth, we believe that some mild hepatic poison has been acting on a constitutionally inadequate and susceptible hepatic cell. The curious tendency of the jaundice to appear or to increase following emotion, nervous breakdowns, "bilious attacks," constipation or diarrhea indicates that the mechanism for excretion of bilirubin in these cases is easily influenced. The occasional occurrence of slight retention of dye, shown by the bromsulphalein test, and the occasional change of an indirect reaction to a delayed direct reaction are further evidence that actual hepatic dysfunction exists.

Especially interesting is the so-called nervous icterus which occurs in this type of hepatic dysfunction. We had as patients a physician who turned yellow after a day of excitement, a housewife whose slight chronic icterus increased when she became angry, and a woman whose chronic icterus began after a fright, all of these cases may represent examples of hepatic dysfunction due to emotion. Chronietzka mentioned a patient who turned yellow following an attack of renal colic. He also demonstrated the influence of nervousness on the content of bilirubin in the serum in the subicteric range. He found that in some cases concentrations that had been increased above normal on admission returned to normal a few days after registration. Lppinger and Hess¹² assumed that such spasmodic and emotional icterus was due to constitutional vagotonia, with spasm of the common duct of vagal origin.

Dysfunction secondary to hepatic disease appears in cases of toxic hepatitis due to chronic passive congestion and hyperthyroidism, in cases in which there are metastatic malignant growths, and in compensated biliary and portal cirrhosis (table 1). In our opinion, hepatic dysfunction in these cases of hyperthyroidism is due to hepatic injury of slight degree, but of the type described by Weller¹³ and by Beaver and Pemberton.¹⁴ The presence of hepatic dysfunction in the various types of cases in this group is confirmed by the almost universal occurrence of some degree of retention of dye.

Dysfunction secondary to hepatic injury persists after disappearance of the acute phase of toxic hepatitis and biliary disease. In one case, dysfunction, as measured by the concentration of serum bilirubin and by the bromsulphalein test, persisted months after the jaundice of toxic hepatitis resulting from poisoning by cinchophen had disappeared. In other cases a history of chronic or intermittent jaundice was obtained. One such patient, who was a missionary, stated that jaundice had first appeared when he went to the tropics, and that the jaundice reappeared whenever he returned there. In another case the initial hepatic injury seems to have been the result of hyperthyroidism, and in others of catarrhal or infectious jaundice.

CASE 3—A man, aged 36, complained of jaundice. The initial attack, at the age of 18 years had been severe and accompanied by high fever. Since that time his sclerae had been yellow at times, especially when the infection of the upper part of the respiratory tract was present. The last attack had begun six weeks before we saw him and had lasted one week. On examination, jaundice was not discernible. Anemia, erythro-

cytes of abnormal morphology or fragility, and an abnormal percentage of reticulated cells, were absent. The reading for bilirubin was 21 mg per hundred cubic centimeters and the van den Bergh reaction was indirect. The bromsulphalein test of hepatic function gave no evidence of retention of dye. Roentgenologic examinations of the gallbladder, after administration of dye, disclosed that the organ was functioning normally.

In this case the initial attacks as well as subsequent attacks of jaundice suggested an infectious condition. The laboratory examinations excluded chronic hemolytic icterus. In other cases, occasional slight retention of dye and a delayed-direct van den Bergh reaction support in small measure our conception of persisting hepatic dysfunction in these cases. Similarly, in all but four cases of disease of the biliary tract the history of attacks of jaundice, and the changes found at the operating table, cholangitis or hepatitis, point to previous hepatic injury, with residual injury to the liver possibly explaining the increased concentration of bilirubin. Hurst¹⁵ demonstrated hepatic dysfunction associated with cholecystitis by means of the levulose tolerance test and expressed the belief that in such cases medical treatment should follow surgical removal of the offending organ.

The decision that constitutional dysfunction, or dysfunction secondary to hepatic injury, accounts for the increased concentration of bilirubin in the individual cases of this series presenting organic disease is a difficult one to make. In some cases of organic disease the history of the jaundice permits it to be classified as constitutional. Thus, we know that the jaundice had been present in one case since birth, and in another for six years, before the development of hyperthyroidism. In two cases the jaundice had appeared at birth and had lasted for thirty-five and forty years before the appearance of symptoms referable to the gallbladder. Similarly, in five cases the jaundice, which had begun at the respective ages of 14, 20, 24, 25 and 30 years, had lasted respectively thirty-six, seven, six, ten and nineteen years before the appearance of disease of the gallbladder. Concerning these nine cases there does not seem to be much doubt that constitutional dysfunction antedated the appearance of organic injury. In the cases of disease of the gallbladder and liver without jaundice, it is often impossible to distinguish the two types of dysfunction, it is quite likely that a degree of constitutional dysfunction insufficient to produce jaundice had existed before development of the biliary and hepatic disease in some of these cases also.

Clinical Importance—Eight patients who had constitutional hepatic dysfunction made no complaints, and no disease was discoverable by physical and laboratory examinations. Six of the eight wished to be examined only because of the jaundice. It appears that constitutional hepatic dysfunction is compatible with health.

Patients with constitutional dysfunction of the liver seem to develop functional disease frequently. The disease was so classified in twenty-one cases. This series cannot be studied statistically, however, as a control series was not available and patients with functional disease make up a high percentage of any group. The data therefore do not permit the conclusion that constitutional hepatic dysfunction predisposes to functional disease. For like reason conclusions regarding

the relationship between duodenal ulcer and constitutional dysfunction cannot be made.

It does seem significant however that, in ten, or 29 per cent, of the thirty-four patients who had jaundice of the constitutional hepatic type, disease of the gallbladder eventually developed. The duration of the jaundice before the development of symptoms of disease of the gallbladder in these cases excludes the gallbladder as the cause of the jaundice. The high percentage of this group in which disease of the gallbladder developed may mean that constitutional hepatic dysfunction, at least of the grade capable of producing jaundice, predisposed to disease of the gallbladder.

Patients with either constitutional or acquired types of hepatic dysfunction frequently complain of "biliousness." Migraine and episodes of exhaustion together with anorexia, dull headaches, bad taste in the mouth and constipation, are the syndromes to which laymen apply the term "biliousness." Hunt¹⁶ recently has reviewed the relation of migraine to disease of the gallbladder and liver. He has concluded, contrary to the opinions of others, that dysfunction of the gallbladder is not the cause but may be the result of repeated migrainous attacks. He has suggested that some hepatic dysfunction may be the cause of migraine in certain cases, and he has found support for this belief in the attacks of migraine provoked by magnesium sulphate introduced into the duodenum of patients who have undergone cholecystectomy, and also in the occasional good results that have followed treatment of migraine with bile salts. McClure and Huntsinger¹⁷ claim to have demonstrated hepatic dysfunction in 90 per cent of seventy-two cases of migraine. Diamond¹⁸ found elevated concentrations of bilirubin among thirty-five of thirty-eight patients who had migraine, he believed this to be evidence of hepatic toxemia. Certainly a relationship between hepatic dysfunction and migraine exists in some cases, but it is difficult to separate cause and effect. The sequence of headache and jaundice in the cases of this series suggests that the sympathetic storm, of which the headache is one expression, likewise provokes hepatic dysfunction.

Case 4 will illustrate the second syndrome described by laymen as biliousness.

CASE 4—A man, aged 24, first registered at the clinic in September 1919. He complained of jaundice and biliousness. His sclerae had always been yellow, just as his father's had been. Every few weeks, episodes of exhaustion, mental torpor, headache, constipation and gaseous indigestion occurred, during which exacerbation of the icterus took place. The attacks were precipitated by overeating. The slightly yellowish tint of the skin and sclerae was the only significant physical finding. The fragility of the erythrocytes was normal, and there was no anemia.

The patient returned again in 1923 and the symptoms and conditions found were identical. In addition, the urine contained a trace of urobilin and urobilinogen. The percentage of reticulated cells was 0.6 and 0.7. We last saw the patient in 1930, when he was 35 years of age. His condition was the same as before. No evidence of hemolytic icterus could be obtained in the laboratory. The readings for serum bilirubin were 3.4 and 1.9 mg per hundred cubic centimeters. The van den Bergh reaction was indirect. A roentgenogram of the

gallbladder after oral administration of dye indicated that the organ was functioning normally

The patient in the case just reported probably had constitutional hepatic dysfunction. Patients who have hepatitis persisting after severe hepatic injury also complain of jaundice and biliousness. The attacks were said to have been precipitated by the eating of rich, greasy or fatty foods, or by constipation. In some cases, slight enlargement or tenderness of the liver, a history of having passed light-colored stools, as well as the appearance of jaundice, focused the attention on the liver as the offending organ. It is not difficult to understand why such patients are convinced that the liver is "out of order." It is also easy to see why patients who make similar complaints, but who do not have visible jaundice, likewise blame the liver for their disability. In the eyes of members of the medical profession, however, a conception of mild or functional disturbance of the liver has fallen into disrepute. However, Hurst, that able exponent of scientific medicine, has expressed the belief that such dysfunction exists at times. He has called attention to its occurrence in cases of acute alcoholism before the development of cirrhosis, in cases of hepatitis developing in the tropics, believed by him to be a form of amebic hepatitis, and in cases of cholecystitis in which symptoms persist after cholecystectomy. It does seem that the liver plays a part in producing the jaundice, but it is not always clear that the liver is the sole cause of the symptoms. In some of our cases, hepatic dysfunction, indicated by increased concentration of bilirubin, seemed to be merely the result of nervous influences.

The Significance of the Indirect van den Bergh Reaction—The indirect character of the van den Bergh reaction may be cited as evidence that hepatic dysfunction does not account for the increased concentration of bilirubin in these cases. According to the accepted teachings, the indirect van den Bergh reaction is found in the serum of normal patients and of those who have hemolytic disease, when hepatic injury takes place, the indirect reaction changes to the direct. We have seen, however, increased concentrations of bilirubin in serum giving an indirect van den Bergh reaction return to normal concentrations as healing took place in the liver that had been injured by chronic passive congestion and hyperthyroidism. In these cases the van den Bergh reaction may not be direct at any time in the course of the illness. In other cases we have seen the van den Bergh reaction change from direct to indirect, and the increased concentration of bilirubin subsequently return to normal during convalescence from hepatic parenchymal injury. A case of hepatitis caused by cinchophen in this series is a case in point. This patient had a severe attack of cinchophen hepatitis in December 1930 and January 1931. April 8, 1931, the reading for bilirubin was 2.2 mg per hundred cubic centimeters of serum, and the van den Bergh reaction was indirect. Retention of dye was graded 3. June 10, the reading for serum bilirubin was 1.8 mg per hundred cubic centimeters, and retention of dye was graded 1. August 18, the reading for serum bilirubin was 1.4 mg, and retention of dye was graded 0. It is significant that parallelism exists between the fall in concentration of bilirubin and the return of normal hepatic function, as indicated by the degree of retention of dye. In other cases the change of an indirect to a delayed-direct reaction shows that some process is at work which can change the reaction. A change in type from indirect

to delayed-direct or to direct reaction rarely takes place in constitutional jaundice and often is the case in jaundice due to organic disease. In short, an indirect van den Bergh reaction may occur in hepatic disease even when mild retardation of excretion of bilirubin occurs. In fact, we believe that a concentration of bilirubin, increased over normal, is good evidence of hepatic dysfunction, regardless of the type of van den Bergh reaction, provided hemolytic disease is not present, and, as we shall see, it may be good evidence of hepatic dysfunction in certain cases of hemolytic disease.

INCREASED CONCENTRATIONS OF SERUM BILIRUBIN IN CASES IN WHICH HEMOLYTIC DISEASE WAS PRESENT

Hepatic dysfunction in hemolytic disease has received scant attention. Excess of bilirubin in the blood serum is commonly considered to be the result of increased hemolysis. Rich,¹⁹ however, has expressed the opinion that conditions which are responsible for increased production of bile pigment are almost always associated with conditions that depress the excretory function of the liver. Well known but little emphasized pathologic changes are leukemic infiltrations in leukemia, hepatitis in malaria, severe infections and intoxication, cirrhosis in splenic anemia, and the fatty liver in pernicious anemia. The hepatic lesions in chronic hemolytic icterus are not often considered. Giffin²⁰ and Pemberton²¹ are among the authors who have given the matter some attention. Giffin²⁰ pointed out that hepatic injury develops in this disease. Pemberton²¹ in a recent study, reported that the operative data were suggestive of hepatic disease in fifty-five of 113 cases. Pathologic changes ranged from adhesion to the surrounding organs, enlargement, congestion and increased density to well marked cirrhosis with ascites. Such hepatic injury leads to changes in results of tests of hepatic function, indicating dysfunction. Retention of dye in varying degrees may occur in most types of hemolytic disease. This is especially true in cases of chronic hemolytic icterus, concerning which Giffin²² has the impression that retention of dye, graded 1 or 2, is usually present before cirrhosis develops. In all cases of this series in which a bromsulphalein test was done, retention of dye was graded 2. In the great majority of cases of chronic hemolytic icterus the direct van den Bergh test is absent. However, in an occasional case the reaction becomes delayed-direct or direct. Such reactions were not due to obstructive jaundice in Pemberton's series. They are reliable evidence of hepatic injury when disease of the bile ducts is not present. They should be so interpreted here.

The nature of the hepatic injury is questionable. Rich has expressed the belief that anoxemia due to the anemia injures the hepatic cells, producing central necrosis and a depression of excretory function. The anemia did not seem marked enough to explain the hepatic injury in all the cases of this series. However, we did not determine whether or not anoxemia was present. Rich has likewise pointed out that clinically and experimentally the reserve excretory power of the liver is so great that excessive formation of bilirubin alone rarely accounts for the jaundice, and that a

22 Giffin H Z Personal communication to the authors

depression of excretory hepatic function must likewise be present. The evidence for the presence of hepatic injury and dysfunction in these cases is so good that we agree that it, as well as excessive hemolysis, may be a cause of an increase in the concentration of bilirubin, in a majority of cases of hemolytic disease.

SUMMARY AND CONCLUSIONS

An analysis of 214 cases was made in which the concentration of the bilirubin was 20 mg per hundred cubic centimeters of serum or greater, and in which the van den Bergh reaction was indirect. In 138 cases, hemolytic disease was absent, in seventy-six cases it was present.

Increased concentrations of bilirubin in the cases in which hemolytic disease is absent means in our opinion, hepatic dysfunction. The dysfunction has been found to be either constitutional or secondary to hepatic injury. In hemolytic disease, excessive hemolysis is the accepted explanation of the increased concentration of bilirubin. The almost universal presence of some degree of hepatic injury associated with hemolytic disease suggests, however, that hepatic injury and dysfunction may also be partly responsible for elevation of the concentration of bilirubin.

The indirect reaction supposedly rules out the presence of hepatic injury. Actually, however, bona fide hepatic disease has been demonstrated in many cases of this series. Moreover, we have witnessed the van den Bergh reaction change from direct to indirect during convalescence from the hepatic injury while increased concentration of bilirubin was still present. The concentration of bilirubin subsequently returned to normal. We have also seen increased concentrations of bilirubin in serum which never had given a direct van den Bergh reaction return to normal concentration as the process of reparation in the liver proceeded. For these reasons, it appears that an indirect reaction in serum containing bilirubin in amounts more than normal does not always mean hemolytic disease and in fact may definitely point to associated hepatic injury.

Some patients who complain of being bilious actually have slight hepatic dysfunction. The dysfunction may be constitutional or secondary to hepatic injury. It is not clear that all symptoms actually are due to the hepatic dysfunction, but it is probable in some instances that the hepatic dysfunction may be only one of the manifestations of a widespread sympathetic or toxic reaction.

The evidence strongly suggests that among patients who have constitutional dysfunction of the liver, at least of a degree great enough to produce jaundice, disease of the gallbladder is prone to develop. Of the cases studied, in 29 per cent cholecystic disease already has developed. Many of the remaining patients are young. The percentage may increase as these patients grow older.

The mechanism for secretion of bilirubin is a sensitive one. It is influenced by emotion and by disturbances of the sympathetic nervous system, as well as by very minor degrees of hepatic injury. An increased concentration of bilirubin may be the one laboratory evidence of dysfunction and it should be used more widely. It will in all probability disclose many unsuspected cases of mild functional and organic disturbances of the liver as well as a group of individuals of a constitutional type especially susceptible to disease of the gallbladder.

ABSTRACT OF DISCUSSION

ON PAPERS OF DRs MANN AND BOLLMAN AND
DRs ROZENDAAL, COMFORT AND SNELL

Dr I S RAYDIN, Philadelphia. In 1925 Dr Muller, Dr Elizabeth Glenn Raydin and I presented before this association some studies on the serum bilirubin in which the van den Bergh reaction for the quantitative determination was used. At that time the opinion was more or less general that the Meulengracht test was simpler and offered just as much information as did the method of van den Bergh. Of this we have never been convinced since a variety of pigments in foods may enter the blood stream and cause a rise in the Meulengracht figures, while the diazo reaction remains unaffected by them. A possible explanation for the production of jaundice following the prolonged intravenous administration of dextrose in large amounts may be found in the work of Forsgren, who showed that glycogen storage and bile formation do not take place at the same time. The patient with an obstruction of the common bile duct presents a serious surgical problem. Of major import is the tendency of these patients to bleed following operation. There is no marked change in the serum calcium or fibrinogen in these patients. Several years ago we reported that dextrose reduced the tendency to postoperative hemorrhage and this has now been adequately confirmed by other investigators. We have therefore given up the use of calcium in the preoperative preparation of jaundiced patients. Drs Mann and Bollman have called attention to the effect of the absence of bile in the intestinal tract. There can be no doubt that the daily restoration of from 150 to 400 cc of bile into the duodenum of the patient is of considerable value when the total bile is being diverted externally. The asthenia that so frequently is observed following common duct drainage is markedly reduced by this procedure. The edema that is seen in certain of these cases and is in part associated with a diminution of the plasma protein can be controlled by adequate diet and the addition of bile to the gastro-intestinal tract. However, certain of the instances of bile ascites are also in part due to a rise in the portal venous pressure incident to the hepatic ductal obstruction when sufficient collateral circulation does not take place, since ductal obstruction results in portal venous stasis. In the patient whose common duct has been obstructed for a considerable period and whose gallbladder is damaged, the bile salts, as measured by the Gregory-Pascoe reaction, disappear from the bile drainage from the liver immediately after the operation and may not again appear for some time. We believe that their reappearance indicates a return of the liver to normal activity.

Dr A C IVEY, Chicago. One point in the paper by Drs Mann and Bollman is in regard to the occurrence of peptic ulcer with obstruction of the common bile duct. My associates and I have been able to confirm that finding in our laboratory. If one produces, in a dog, a condition that leads to a chronic biliary tract infection, with a mild hepatitis, and an elevated icteric index, the incidence of ulcers in the various series amounts to from 40 to 80 per cent. We are now observing a series of animals in our laboratory in which we have performed a cholecystoduodenostomy with pyloric exclusion, and gastro-jejunostomy, and so far the incidence of jejunal ulcer is 60 per cent. As time goes on, I believe that the internist will find chronic biliary tract infection to be associated with ulcer of the duodenum more frequently than he has heretofore suspected. Another point that Drs Mann and Bollman pointed out is that the excessive administration of dextrose in an animal with a subnormal or even a normal functioning liver may cause jaundice. This is interesting in regard to the effect of carbohydrates on the formation of bile. Carbohydrates either have no effect on or depress the formation of bile. In other words, the act of storing of glycogen tends to suppress the elimination of bilirubin. This is evidence of a differential functional activity. Another instance is that, if one injects some bilirubin and bile salts intravenously at the same time, there results an increase in the formation of a light, limpid bile, but there is a retention of the injected bilirubin in the blood stream. The administration of bile to biliary fistula patients is a sound procedure, but according to experiments that we have performed on dogs the administration of bile to subjects with complete obstructive jaundice is deleterious. Whether or

not bile salts should be administered to increase the rate of bilirubin elimination after a common bile duct obstruction has been relieved I think is a matter that has yet to be demonstrated by actual experimental data. The "differential activity" of the liver is important not only from a therapeutic standpoint but also from a diagnostic standpoint. I should like to ask Dr. Mann whether there is any evidence indicating that the consumption of fluids in large quantities might be helpful in promoting the elimination of bile salts and bilirubin in the urine in jaundice cases. I ask that question because it is one that has been put to me frequently. Or does he think that the administration of large quantities of fluid to the jaundiced patient might be harmful in view of the fact that not only the kidney but also the liver is concerned in the maintenance of the water balance of the body, and that there is a tendency to dilution of the blood in the presence of hepatic damage?

DR. M. A. BLANKENHORN, Cleveland. There has been much disappointment in urobilinogen tests in the past because they were too complicated and too much was expected, but, when the simple qualitative test with Ehrlich's reagent is used as a method to demonstrate that bile ducts are draining the test has value. There is, however, a phase in certain liver disorders when no bile is drained into the intestine, in this phase the urobilinogen test is misleading. However, in just that same phase the galactose tolerance test has been found most useful in estimating liver damage. These two tests thus combined overcome each other's difficulties and limitations and should be better than any single test for liver disease and likewise better than employing all the tests in an effort to get an average.

DR. LEON SCHIFF, Cincinnati. I obtained a negative galactose test in twenty of twenty-one cases of obstructive jaundice due mostly to common duct stone and malignant neoplasm of the head of the pancreas. I have had cases of cirrhosis in which a positive test was obtained. In most of these cases the results were negative. A positive test may indicate some associated parenchymal damage to the liver at the time. Banks and Snell have noted the development of a positive test which subsequently disappeared in cases of cirrhosis. I had occasion to make an interesting observation in a case of catarrhal jaundice with a high galactose output. As the jaundice persisted the liver diminished in size, ascites appeared, and a subacute cirrhosis apparently developed. It was interesting to note a drop in the galactose output coincident with the development of the cirrhosis. I believe that the galactose test is of great help in the differential diagnosis of jaundice. If a negative test is obtained on one occasion, the test should be repeated a few days later, particularly if a discrepancy exists between the clinical and laboratory observations.

DR. V. C. ROWLAND, Cleveland. The paper of Drs. Rozen-daal, Comfort and Snell establishes again the limitations of the indirect van den Bergh reaction as specific evidence of hemolytic jaundice. Practically the distribution of bile pigment in clinical jaundice may be determined more simply and satisfactorily by examining the serum (icteric index), the duodenal aspirate, and the feces and urine for bilirubin and urobilin. High bilirubin and bile salt content in serum and urine, with low content in duodenal aspirate and stool, indicates obstructive jaundice more directly than a "direct" van den Bergh. The reverse, a high pigment content in the duodenal aspirate and stool, with a dissociated, acholuric jaundice, indicates a hemolytic disease better than an indirect van den Bergh reaction. The conception of hepatic dysfunction either constitutional or toxic as a basis for latent or slight jaundice in the absence of hemolytic disease is logical and consistent with the physiology of other glandular organs. Toxic and infectious damage and probably also profound emotional disturbances will produce such effects on glandular cells. A bilirubin reading in excess of 15 or 2 mg. per hundred cubic centimeters of serum is abnormal and may be regarded as a sensitive liver function test, so far as the function of pigment excretion is concerned. Since the balance between the formation of bilirubin by the reticulo-endothelial cells and its excretion by the hepatic polygonal cells is disturbed in certain individuals by toxic and nervous factors, the appearance of slight jaundice after an acute digestive upset, however suggestive of gallbladder colic,

cannot be regarded as confirmatory of that diagnosis. This is often assumed when no pathologic condition can be demonstrated by cholecystography or at operation. Further data would be desirable on the probability of late gall tract disorders, especially gallstones, in individuals with a constitutional or acquired hyperbilirubinemia. As the authors indicate, it is difficult to distinguish cause from effect in these cases of latent jaundice, in relation either to organic disease or to associated functional disorders such as migraine. However, Mayo has reported a high percentage of bile pigment calculi in his series of hemolytic jaundice cases. Apparently pigment concentration leads to stone formation. In all probability, obesity and other factors conducive to ordinary cholelithiasis would tend to bring out the latent disorder. Twenty-nine per cent of the authors' patients, many of whom are still young, already show cholelithiasis. This suggests very definitely that there may be a preventive opportunity by personal hygiene and medical management in the chronic cases of latent jaundice. It will be helpful to look on all such cases as presenting potential or incipient liver disease.

DR. I. R. JANKELSON, Boston. There are two possible errors in administering galactose by mouth and estimating the amount secreted in the urine: first, incomplete absorption or delayed absorption from the intestinal tract, second, interfered with or delayed secretion to the urinary tract in the presence of pathologic changes in the tract. In order to obviate these two possible errors I have started an injection of galactose intravenously and determination of the remaining amount of galactose in the blood as a modification of the galactose test. My experience is limited but I find that in normal liver cases at the end of an hour there is no galactose to be found in the circulating blood. In liver disorders there is a variable amount of galactose left in the circulating venous blood at the end of an hour, and in some cases at the end of two hours. The amount of liver damage is judged by the quantity of galactose remaining in the blood at various intervals.

DR. FRANKLIN W. WHITE, Boston. The simplicity of the galactose and urobilinogen tests should be emphasized. They are both tests of the urine that can be easily done and repeated. The expense is very small except for the cost of the galactose. In the Harvard Teaching Service at the Boston City Hospital we have found that urobilinogen is almost invariably absent in the obstructive cases and that it is almost invariably increased in the cases that show much liver cell damage. The two tests back each other up and bridge over the gaps. The more acute the case, the more valuable these two tests become, in the more chronic cases, with opportunities for liver cell regeneration and compensation, the tests are less useful. There are bound to be exceptions. We found one case of subacute yellow atrophy in which both tests were negative. The urobilinogen and galactose tests have had a rather bad name because they have been used indiscriminately in all kinds of liver diseases. Their real value appears when they are used for a definite purpose in a limited group of cases. The urobilinogen tests should be repeated from day to day in order to get the most out of them. There is considerable variation from day to day and from time to time on the same day. I believe these two tests give real diagnostic help and should be used more.

DR. HARRY SHAY, Philadelphia. It may be of interest to point out a few additional facts regarding galactose metabolism in order to convince the most hardened skeptic of the value of the galactose tolerance test in jaundice. To use urinary excretion as a measure of galactose utilization it is obvious that there must be no renal threshold for galactose. That fact was adequately demonstrated some time ago by Folin and Berglund, and has been more recently by Harding and Van Nostrand. I bring this up because of the recent tendency, as indicated by Dr. Jankelson's discussion, to utilize the blood galactose curve in preference to the urinary excretion. Since it is reasonably certain that there is no renal threshold for galactose, I cannot see the necessity of complicating a simple laboratory procedure and converting it to one almost prohibitive for routine clinical use. Further, the determination of the blood sugar would be of no value unless the galactose level was separately determined since the metabolic factors

are not the same for galactose and dextrose. The other question of great importance is whether galactose after it passes the liver is utilized by any other tissue of the body. In a study, which my associates and I reported in 1931 it was concluded that galactose after it passed the liver was practically not utilizable by any other tissue. This has received further support in a recent work of Arcq in the *Belgian Review of Medical Sciences* in which in dogs he studied liver and muscle glycogen following intravenous injection and after oral administration of galactose. He found that in both instances the liver glycogen was definitely increased while muscle glycogen was at no time enhanced. Laquer and Meyer studying lactic acid formation by muscle suspensions found that fructose and dextrose were converted into lactic acid quantitatively while galactose remained unchanged. If the tissues other than the liver cannot utilize galactose as such, if they cannot convert galactose into glycogen or lactic acid and since there is no kidney threshold for galactose it becomes obvious that galactose is a sugar that is ideally suited for testing the carbohydrate function of the liver. This opinion has been confirmed by Frank C Mann in his studies on dogs.

DR. NORMAN W. ELTON, Reading, Pa. Drs. Rozendaal, Comfort and Snell used the name of Lcpehne in connection with the ring test modification of the van den Bergh reaction. This modification is extremely important and is of great value in the detection of positive reactions that are entirely missed by the ordinary technic. I wish to suggest that the name of Lcpehne be deleted from the terminology of the ring test, for in his original and only communication in which the method is mentioned he states that in his experience it afforded no advantage over the original technic in dealing with serums of low bilirubin content that it was not essential with serums of high bilirubin content and that he had discontinued its use. The true value of the ring test was not appreciated by Lcpehne, and this modification should be known simply as the ring test as advocated by Magath.

DR. FRANK SMITHIES, Chicago. Regarding the paper of Drs. Mann and Bollman I think that it has been proved that when the common operative treatment for peptic ulcer consisted in nothing more than a gastrojejunostomy the greatest number of gastrojejunal ulcers was experienced largely because of the reflux of bile and pancreatic juice over the anastomosis. Since plastic or local operations on the ulcers have been performed gastrojejunal ulcers have been less frequent. In the paper of Drs. Rozendaal, Comfort and Snell ancient wisdom is emphasized namely people for two or three centuries have considered themselves bilious when the liver function was inefficient. Recent special tests have proved the correctness of their views. I wish to ask the following questions. In this group of patients were any observations made with regard to gastric secretory function following full meals, with or without stimuli? It appears to me that there is much significance in the relationships between velocity and quantity of the gastric and pancreatic secretion and the biliary tract secretion. Have any continuous observations been made on the same patients over a long period of time in order to observe what happens to note what may be the variation in such individuals in relationship to health or to dysfunction? With regard to urobilinogen and urobilin in pernicious anemia in 103 cases of pernicious anemia I found that at some time ninety-one of the patients showed such evidences of hemolysis and that 43 per cent showed it constantly. There is a response varying with the clinical remissions and recrudescences of the disorder in the qualitative and even the quantitative evidences of hemolysis, clinical or from the laboratory side. Twenty-two years ago I reported a group of cases which I called cachexias of malnutrition and in that group I fed the patients amino acids and bile at first recovered from human beings and then later the amino acids artificially produced. This procedure was followed by rather striking clinical improvement. Practically all these patients were what were known as chronic bilious or liver cases.

DR. FRANK S. PERKIN, Detroit. I should like to substantiate the remarks of Drs. Rozendaal, Comfort and Snell in regard to a wider use of the serum bilirubin test and its clinical applications. Some eight years ago I became particularly

interested in the fact that my normals were constant and that the range of normal was exceedingly small. An occasional individual in any series of normals would appear with a comparatively high reading. These were sometimes unexplainable. In other cases there were suggestive clues to previous liver damage, however these cases were rare. Consequently, it was felt that rises above the normal level were exceedingly significant. Various clinical applications were suggested. Apparently the test has fallen into disuse in many centers probably because too wide inferences were drawn and too much information was sought. It has definite clinical applications which are very valuable for instance, in foretelling toxic damage to the liver in the use of the various drugs particularly of arsenic in advance of any clinical evidence. Its routine use in cases in which large amounts of arsenic are being given is very valuable. Its use is also valuable when it is felt that cinchophen should be used. Here one can tell early liver damage. Rises in slight degrees from the normal have been seen in anemias and it afforded a method of differentiation between a primary and a secondary anemia. Its use has likewise been suggested in lead poisoning.

DR. F. C. MANN, Rochester, Minn. To answer the questions we do administer fluids, but I can't answer the question whether or not they increase the elimination of bile salts.

DR. DAVID H. ROSENBERG, Chicago. Dr. Shay was the first in this country to call attention to the value of the galactose test in the diagnosis of painless jaundice. The appearance of positive galactose tests in cirrhosis seems to depend on the degree of balance that obtains between the amount of regeneration and the amount of destruction in the liver parenchyma. Dr. Rowland suggested passing a duodenal tube in order to note the presence of bile in the duodenum. It is much simpler and easier to perform a urobilinogen test on the urine for the discomfort of intubation of an anxious excitable patient is thus avoided and a fluoroscopic examination, to determine whether or not the tube has entered the duodenum becomes unnecessary. The use of the duodenal tube might well be restricted to those cases in which urobilinogen is constantly absent. The blood galactose test discussed by Dr. Jankelson is technically much more complex than either the urinary galactose or the urobilinogen test. It cannot be performed in the office and although perhaps more accurate than the urinary galactose test as an index of liver function seems to possess no practical advantage over the latter in differentiating these two types of jaundice.

DR. M. W. COMFORT, Rochester, Minn. Mild hepatic dysfunction has been recognized for many years. Many patients continue to assert that they are 'bilious' in spite of the current disrepute in which this term is held by members of the medical profession. The quantitative estimation of the serum bilirubin demonstrates that a mild hepatic dysfunction at times may actually exist in such cases. I am glad to know that Dr. Rowland has likewise encountered such patients. Dr. Smithies' questions are pertinent. Observations on the relationship between velocity and quantity of gastric pancreatic and biliary secretions should be but so far as I am aware have not yet been made. Gilbert and his associates thought that patients who had bilirubin present in the serum in a quantity above normal were susceptible to many diseases. So far we have no evidence that they are especially prone to have diseases other than cholelithiasis and cholecystitis. Both the congenital and acquired types are compatible with health.

Discovery of Reflex Action.—In 1784 a professor of anatomy in Moravia wrote a very short account of the nervous system and in attempting to explain how it worked said that physical and mental stimuli acting upon ascending nerves are conveyed directly through the ganglia and network of nerve threads to be reflected thence by means of descending nerves with a result in action. This wonderful discovery in thought of reflex action arrived at so far as we know without definite experiment is the foundation of most of what we now know concerning the way in which the nervous system works.—Collier James. NONUNION IN FRACTURE OF THE SHAFT OF THE HUMERUS

REPORT OF FIVE CASES

JAMES WARREN SEVER, MD
BOSTON

It is common knowledge that delayed union and nonunion occur more often in the shaft of the humerus, after fracture, than in any other long bone. This statement is, I believe, true only of fractures occurring in the middle third of the shaft, and transverse in direction. Spiral fractures that involve this region may be slow to unite, but so far I have known of no nonunions, or pseudo-arthroses. Of the following cases, three occurred in my practice and two are, fortunately for me the misfortunes of others.

Case 1 is a report of historical interest in which a fracture of the humerus, with two subsequent refractures, went on to nonunion and complete absorption of the shaft.

My interest in this subject led me to the Warren Museum at the Harvard Medical School where I found the specimen (fig 1) as well as a picture of the patient before his death (fig 2).

The history of the case was reported¹ first briefly in July 1838 and is as follows:

In the autumn of 1819, Mr. Brown, a worthy and industrious provision dealer in Derne St, now 36 years of age, in his 18th year had the misfortune to have the right humerus fractured nearly in the middle. He was holding under disadvantages, an enraged cow by the horns, and in some unexpected movement of the unruly animal, both fell, and the bone of his right arm was broken by the fall. Under the care of a judicious surgeon a reunion was favorably going on, but before the curative process had been completed Mr. Brown accidentally had another fall, and broke open the old fracture again. A short time later he slipped on the floor and suffered a third refracture in the same place. The last accident was not more than two months after the first. Notwithstanding a most vigilant and untiring devotion to the injured limb, the divided extremities would not adhere, and to the surprise of the medical attendant, the shaft of each part of the divided bone began to diminish in size, and shorten in length. By a gradual action of the absorbents the whole of the arm-bone, between the shoulder

Fig 1—Arm of Mr. Brown (specimen in Warren Museum)

and elbow was at length completely removed, and that too without any open ulcer so not a single vestige was left.

In spite of his having no bone in the upper arm, it was observed that this man could write, hoe, rake, cut wood and carry a pail of water. One of his amusements seems to have been to twist his arm once and a half around in one direction, then taking up a pail of water to let it untwist, and twist once

and a half around in the other direction. He could not flex the forearm on the upper arm at will, nor could he extend the forearm when flexed.

After his death in the Boston Lunatic Hospital, in February 1871 the arm was obtained and prepared by Dr. Thomas Dwight² of the Harvard Medical School, where it now is (figs 1 and 2).

This case fortunately represents a unique condition, which, so far as I can find, cannot be duplicated. This

Fig 2—Mr. Brown (from old tintype showing sides reversed)

complete absorption must have been due to several factors. First, nonunion due to frequent fracture and the loss of the "stimulus of incompleteness" as spoken of by Hunter. Second, marked atrophy of disuse. Third, probably vital interference with endosteal as well as with periosteal blood supply. Fourth, the fact that the man became insane, from what cause could not be determined, this may have been a factor, especially if his condition was syphilitic in origin, though I never heard of syphilis affecting bone to the extent that it caused complete absorption. Pathologically, the case remains a mystery.

CASE 2—C. L., a woman, aged 35, first broke the left humerus at the age of 17 years. This was a compound fracture. What happened after that is rather vague but so far as I could find out the fracture was reduced, nonunion followed, and then a plate was applied. This became septic and had to be removed. Later a bone graft was applied a graft from the tibia being used. This failed and was followed by the insertion of silver wire which also failed. For the last ten years she has been working as a waitress and states that she can use this arm almost as well as the other.

Examination of the arm shows nonunion of the humerus, with about 2 inches (5 cm.) shortening. She can flex and extend the elbow, she can raise the arm at the shoulder but not to its full extent and only with the upper fragment of

Read before the Section on Orthopedic Surgery at the Eighty-Fifth Annual Session of the American Medical Association, Cleveland, June 14, 1934.

2 Dwight Thomas. Absorption of the Humerus After Fracture. Boston M. & S. J. 10: 245 (Oct 10) 1872

the humerus horizontal. At the site of nonunion there is a right angle deformity, with attempted abduction. Roentgenograms of the arm show considerable bone atrophy, marked separation of the bone ends, and various pieces of what I presume are silver wire. She is unwilling to have any further surgical efforts made in an attempt to give her a more useful arm without a written guaranty for a satisfactory result (figs 3, 4 and 5).

Probably sepsis was the cause of the first failure. The other operations proved futile. Now, with an arm that is useful but far from perfect, she would not be taking an undue chance to have a massive onlay graft applied. The chances for a favorable result are good.

CASE 3—J C W, a woman, aged 59, as the result of an automobile accident, Nov. 18, 1930, suffered a transverse fracture of the middle of the shaft of the right humerus and a comminuted fracture of the head of the left tibia into the knee joint. The fragments of the humerus, which were overriding, were readjusted under gas anesthesia and splinted in the usual

way. Callus at the site of fracture of the humerus failed to form and the patient was operated on, March 19, 1931. Fibrous tissue was found holding the ends of the bone, but no callus. A sliding graft was employed following refreshing and squaring of the bone ends. An arm and body cast was applied. The wound healed by first intention but again bone failed to form and another operation was performed, October 16. At this time the ends of the bone were found tapered off and lying in a thick fibrous capsule filled with a material that resembled synovial fluid. The graft on the lower fragment had apparently united solidly but had become separated from the upper fragment. At this time a step operation was done, with considerable overlapping of the fragments which were fastened together by chromic catgut passed through drill holes. The whole fractured area was then wrapped with a large osteoperiosteal graft from the tibia (fig 6) and reinforced by another large osteoperiosteal graft, laid on top and held in place by circular ligatures. An arm and

Fig 3 (case 2)—Appearance of patient

body cast was applied. This cast was removed December 4 and a splint applied. At this time, although the roentgenogram showed some callus, there was no union clinically. In spite of the long splinting, she again went on to complete nonunion and when last seen in April 1934, showed considerable disability of the arm. She could not get the hand back of her head and had considerable difficulty in getting her right hand on to the left shoulder. The arm was shorter and abduction was impossible. Roentgenograms at this time showed the condition of the bone (figs 7, 8, 9 and 10). She has refused further attempts to correct the condition.

I believed that this woman failed to get a satisfactory result from either operation for the following reasons: At the first operation a sliding graft was used. This may not have been from good viable bone and the fixation of the graft and fracture may not have been rigid enough. Hence the possibility of failure. At the

second operation, good bone was used. The step was cut deeply but was held only by catgut. In spite of good approximation and reinforcement by two large osteoperiosteal grafts, nonunion followed. This may have been due to poor fixation or to a cause of nonunion that mocks all theories, as some one has said.

CASE 4—G W, a man, aged 50, was caught by a pulley belt and twisted around a shafting several times and then dropped to the floor, March 27, 1931. He suffered a Potts'

Fig 4 (case 2)—Condition of bone, Jan 30 1934 arm extended

Fig 5 (case 2)—Condition of bone Jan 30 1934 arm flexed

fracture of the right ankle, a comminuted fracture of the left knee joint, six fractured ribs, and a comminuted fracture of the middle of the right humerus. All this was followed by pneumonia. When I first saw him June 4, there was no union

Fig 6 (case 3)—Details of operation Oct 16 1931. A sac with fluid. B thick fibrous tissue. C old graft. D lapped and counter sunk. E two strands of chromic drill hole. F heavy osteoperiosteal graft wrapped about from right tibia and tied in place.

of the humerus or of the right ankle. The humerus was operated on June 19. Fibrous union was found which was cleaned out, and a step approximation of the fragments was made. This step was held by four heavy kangaroo sutures passed through drill holes. An arm and body cast was applied for fixation which he wore until about the middle of August 1931. On September 16 there was no evidence of union.

He was reoperated on, November 10. The ends of the bone were found to be surrounded by a large amount of fibrous tissue, which was removed, and the ends were refreshed. New steps were made and held by heavy chromic catgut passed through two drill holes. A beef-bone screw was also inserted for better fixation.

Fig. 7 (case 3) — Appearance of arm in April 1934

The whole area was surrounded by a heavy osteoperiosteal graft from the tibia. The fixation was good and the ends of the bone were in good position. An arm and body spica was applied, which he wore until Jan. 31, 1932, at which time the arm seemed quite solid.

April 16, he still had solid union of the arm but on November 7 roentgenograms again showed nonunion which was present when last seen, Jan. 8, 1934. The arm at that time was 2 inches short (figs. 11, 12 and 13).

Here is a person who suffered multiple fractures. In the literature I can find nothing but general statements in re-

gard to the effect of trauma as a causative factor in nonunion. Just what trauma per se does to the reparative ability of the periosteum or endosteum is apparently

Fig. 8 (case 3) — Condition of bone, Nov. 18, 1930

not known. Multiple fractures must seriously deplete or impair the ability of the bodily chemistry to produce enough new bone at various places when there is such an extra demand.

As a result of the fracture of the ankle, there was nonunion of the internal malleolus, which later had to be pegged. I cannot account for the breaking up or

gradual dissolution of the union following the second step of operation.

CASE 5—A. H., a man, aged 20, fell from a ladder, Sept. 28, 1932, and fractured the right humerus at about the middle. The arm was set and a splint applied, which he wore for three months, without any evidence of union. During this period he had recovered from a musculospiral paralysis. I saw him first May 16, 1933, and advised a bone graft, which was done, June 6. A large, massive graft was removed from the tibia, and countersunk into the humerus, after the ends had been freshened. The graft was held in place by four heavy chromic gut sutures, passed through drill holes. A body and arm cast was then applied, which he wore until July 29. On this date there seemed to be good union clinically and roentgenologically. When seen again November 22 nonunion had recurred (figs. 14 and 15).

This boy did well and had apparently good union until I lost sight of him during the summer. He was in the hands, then, of a vigorous physical therapist, and probably the treatment, combined with the soft callus, resulted in fracture and absorption of the graft and failure of union. I believe that if longer fixation had been carried out and physical therapy had been neglected he would have gone on to firm and permanent union.

Now what do these cases prove? First, I believe that one should report failures as well as successes and, second, I believe that there must be some intrinsic cause for nonunion in fractures of the humerus that is not wholly understood.

Trauma from the accident itself, may so destroy the power of bone repair that union is delayed or prevented. Interference with the blood supply through the tearing of the nutrient artery may be another factor. Lack of adequate fixation, which is of the greatest importance, is another probable cause, and in the operative repair, primary internal as well as secondary external fixation is essential for a long period. However, it is practically impossible to immobilize the humerus completely in any type of external apparatus. In spite of an adequate consideration of all these factors, recurrent nonunion may, and does, occur in a certain percentage of cases.

Lack of callus formation and interposition of tissue are often factors that must be considered. The second cause is of course removed at operation, but lack of callus formation cannot be foretold. In none of these cases was there any endocrine disturbance or any abnormality in the blood chemistry. The fractures in these cases were located at about the entrance of the main nutrient artery and so may have cut off this supply.

Fig. 9 (case 3) — Condition of bone, Dec. 20, 1933

However as Kolodny³ has pointed out if the periosteal blood supply is adequate, normal union in fractures should take place, regardless of the endosteal blood supply. In these cases the endosteal supply may have been seriously impaired but the periosteal supply seemed to be ample, except as impaired by operative procedure.

Haas⁴ believes that the chief source of osteogenic cells for the repair of fractures is from the osteoblasts of the periosteum and the endosteum. The periosteum plays a relatively more active part than the endosteum. Whether direct and severe trauma, such as is suffered in modern automobile accidents, causes loss of vitality in either or both of these structures, is uncertain but may be a factor in delayed union or nonunion. In my experience with a large number of fractures of all kinds from automobile accidents delayed union in the long bones is not uncommon and more frequent than in fractures occurring without such direct trauma.

Mock⁵ states that the consensus of all investigators is that the periosteum contains the chief osteogenic ability, and that repair can be obtained more rapidly by the use of an osteoperiosteal graft than by an autogenous bone graft alone. Except in one instance, namely, in case 4, there is no evidence of any periosteal activity in the reparative process that did occur.

On the other hand Moore and Corbett⁶ believe that periosteum is not an essential element in the healing of bone and Galle and Robertson⁷ also believe that the periosteum as such is not osteogenic and should not be depended on under any circumstances to assist.

They believe, however in the production of new bone that from a clinical standpoint its presence is of importance through its control as a limiting membrane of the circulation in a living bone.

I like to agree with the Browns⁸ that the periosteum is merely a limiting membrane and a protection to a graft while circulation is being established from the living bone, and that it acts also as a protection to the process of regeneration and union between the graft and

the parent bone. This is also Macewen's⁹ statement, who believes that periosteum is only a limiting membrane and has no osteogenic function.

Groves¹⁰ states that the periosteum is the product and not the mother of bone. All osteogenic properties of the periosteum, whether in repair of fractures or in grafting, are due to the presence of the outer layer of the bone cells adherent to its deep surface. Living bone is the chief source and origin of callus, which grows mainly from its outer or periosteal surface and, to a less extent, from its deep or medullary surface and its cut ends.

I believe that all the discussions and differences of opinion in regard to the value of the periosteum are due to the fact that some surgeons consider

the periosteum, with its layer of cortical, osteogenic cells as an entity and others speak of the periosteum without this layer. With these cortical cells it is an excellent bone producing material, without them it is merely a limiting membrane. Surgeons should decide when talking of the periosteum, as used in bone surgery, to standardize on "periosteum with."

After my experience in these cases, I have come to believe that the only operation probably worth doing is

that advocated, and so well carried out, by Campbell¹¹ and Henderson,¹² namely, the massive or onlay graft, followed by a sufficiently long period of fixation to insure union and to carry one by the period of absorption and possible fracture of the graft. Even this operative procedure is, however, not infallible.

ABSTRACT OF DISCUSSION

DR. W. BARNETT OWEN, Louisville, Ky. Last year before this section I reported nine cases of nonunion of the shaft of the humerus. Eight of the nine cases followed primary operation. One case was treated conservatively. None of the cases reported had been considered under a two year period. I have

Fig. 14 (case 5)—Appearance of patient

three more cases that come under that heading that had not reached two years. I say two years because I have had some cases that appeared as if union would occur six or eight or ten months later. I find that absorption occurs and there is failure to get union. In three of the cases in which I operated, it was necessary to reoperate either because the operation was not properly done or because the vitality of the humerus was such that it did not receive the transplanted bone. In all these instances, the massive onlay graft has been used. Of twelve cases, one presented nonunion and almost complete absorption of the humerus. The other eleven cases so far have remained united. I feel that the early operation, which means trauma of a greater or lesser degree depending on the operator and the type of operation, is a factor in nonunion. I believe that primary

operation for fracture of the humerus should not be performed except for some special reason. I think the first failure, then, is due to lack of reduction and secondly to lack of adequate immobilization for a sufficient length of time. It has been my practice to apply a plaster-of-paris spica of the shoulder, the arm abducted from 90 to 120 degrees, with very little padding being used. It is difficult to immobilize the humerus for a long period. In some cases it has not been satisfactory or sufficient. Perhaps that was a factor in some of the failures. I feel that if the fracture is reduced there will be greater success. I have never seen a case of nonunion of the humerus in a young child. I have never had a failure with a case I have treated for fracture of the humerus primarily. Of all methods, the one Dr. Sever mentioned, that of Campbell and Henderson, is probably the best.

DR. WILLIAM SNEED, New York. I have one hospital in which for the last four years there have been sixty-two fractures of the humerus. Of those there are only fourteen that come under the heading of oblique and transverse. Of the transverse fractures two failed to unite, it was not possible to follow three, and two had delayed union. It is notable that a large number of the transverse fractures failed to unite or had delayed union. The average time of firm union is about six months. I wish to offer a few suggestions that I have found helpful in nonunion and delayed union. I will take, for

Fig. 15 (case 5)—Condition of bone
Nov. 21 1933

example, the complicated, compound fractures. In one notable case the lower third of the humerus was fractured, the biceps muscle was severed and both ends of the bone protruded through into the dirt. I saw this case a month after it was reduced. Three months after there was no callus formation whatever. I offer this for what it is worth. Physical therapy was begun, a window was cut out and diathermy was applied. Calcium carbonate was injected in between the ends of the bone. Within six months there was firm union. No union whatever had resulted before. I have six cases of nonunion that I have treated by this method. By taking a large needle, forcing it in between the bones, putting in the plug and pushing out the little callus, one gets in the needle injecting calcium carbonate. This causes irritation and increases blood supply. Even in the cases in which firm bony union is not obtained, there is enough dense, fibrous union, which acts very well indeed so far as function is concerned.

JEJUNAL ULCER

ROSCOE R. GRAHAM, M.B.

AND

F. I. LEWIS, M.B.

TORONTO, ONT.

A jejunal ulcer is tragic evidence of faulty judgment in the treatment of a patient suffering from gastro-duodenal ulceration.

Our remarks on jejunal ulcer are based on forty-three cases. We have ourselves operated on thirty-three patients. Included in this group were four instances of gastrojejunocholec fistula. We have studied four cases and confirmed the results roentgenographically but as yet have not operated in these cases. We have had an opportunity to study six cases treated by our associates. Five were proved by operation, and one was shown by roentgen studies. Twelve cases occurred following gastro-enterostomy that was performed by us. We have established a follow-up clinic for patients on whom we have operated for gastric or duodenal ulcer. A visit to this clinic includes a physical examination, a complete blood analysis, a fractional gastric analysis and roentgen studies. The latter is a joint examination by the clinician and the radiologist. In this series a true stomal ulcer was present in only one case, in that instance a silk suture was found at the base of the ulcer. In all the others the ulceration was truly jejunal. The ulcerative process would extend up to but not transgress the gastric mucous membrane. The ulcer, with two exceptions, was in the efferent loop of the jejunum.

We believe that the most constant etiologic factor in the formation of a jejunal ulcer is a gastro-enterostomy performed on young patients who for a relatively short time have suffered from an active non-stenosing duodenal ulcer, accompanied by a high percentage of free hydrochloric acid in the gastric contents. We have noted many reports in which jejunal ulcers followed gastro-enterostomy, in which the postoperative gastric analysis showed the absence of free hydrochloric acid. We believe that, unless one controls the position of the duodenal tube by radiographic confirmation of its presence in the stomach and not in the jejunum, the results may be very inaccurate. We have done routine analyses without determining the presence of the tube in the stomach and have found no free hydro

Read before the Section on Surgery, General and Abdominal at the Eighty-Fifth Annual Session of the American Medical Association, Cleveland, June 13, 1934.

chloric acid, but, on repeating this examination, having proved by roentgen examination that the tube was in the stomach and not in the jejunum, we have found free hydrochloric acid present in varying amounts in every patient who presented a stomal ulcer. Further, the accepted rationale of the efficacy of a gastro-enterostomy is not wholly tenable. In other words, while following this operation—theoretically the gastric acidity is decreased by the admixture of bile and pancreatic juice with the gastric contents—we have repeatedly failed to show the presence of bile in the gastric contents when we were certain that the tube was in the stomach and not in the duodenum.

Attempts to occlude the pylorus coincident with a gastro-enterostomy we believe are illogical and productive of a higher incidence of jejunal ulceration than accompanies gastro-enterostomy alone. The brilliant results of gastro-enterostomy for scar stenosis following the healing of a duodenal ulcer are due to factors incidental to the delayed emptying of the stomach: first, the atrophy of the gastric mucous membrane, second, the absence of hypermotility and hypersecretion of the stomach, third, a low incidence of free hydrochloric acid. Artificial stenosis of the pylorus does not in any way produce these secondary factors and further prevents any possible regurgitation of duodenal contents through the pylorus and, instead of an intermittent discharge of acid gastric contents into the jejunum, pours into this portion of the gastro-intestinal tract a continuous content of high acidity. That the jejunum is unable to tolerate continuously such a physiologic state has been proved irrefutably on experimental animals. We have experienced this analogy of artificial

Fig 1 (Mrs G) —Gastro-enterostomy five years before. Jejunal ulcer present. Roentgen examination of a patient who harbored a jejunal ulcer but the ulcer was not visualized with ordinary manipulation.

stenosis in five cases of transection of the stomach after the method of Devine, with the development of five jejunal ulcers in a relatively short time. Further, we believe that a reconstruction of the continuity of the tract by means of an anticolic anastomosis to which is added an entero-enterostomy predisposes to the development of jejunal ulcer.

A jejunal ulcer may present no clinical evidence of its presence until the patient suffers a serious hemor-

rhage or perforation or develops a gastrocolic fistula. When symptoms are present, the pain is different from the indigestion that accompanied the original ulcer. It is of a bizarre, inconstant character. It may radiate down to the pubis, to the loin, to the groin or to the testis. In fact, the clinical diagnosis in one of our cases was ureteral colic, which was excluded only after complete investigation of the urinary tract. Tenderness, when present, is usually above and to the left of the umbilicus, and often the patient complains bitterly of

Fig 2 (Mrs G) —With a pressure bag showing the visualization of the ulcer in the jejunum about three-fourths inch distal to the anastomosis.

pain in the back. The indigestion, while differing from the original disability, is in the early stages characterized by remissions, and the patient experiences relief from food or soda, but after a variable period of discomfort the symptoms become continuous and are relieved by nothing except bed rest. Thus bizarre symptoms of an indigestion in a patient who has had a gastro-enterostomy, which are relieved only by bed rest and which recur when normal activity is assumed, are highly suggestive of the presence of a jejunal ulcer. The symptoms of which these patients complain are so real and definite that the differentiation between an organic lesion and a functional gastric disturbance is not difficult. Thus, when a patient who has had a gastric operation returns with this syndrome, no effort should be spared in attempting to prove the presence or absence of an organic lesion. This is not the usual procedure. The patients are usually granted but a hasty tolerance of their recital of woe and advised to disregard the gastric distress. Unfortunately in many instances, even after the most painstaking and exhaustive investigation, it is impossible to demonstrate positively an organic lesion. This inability to demonstrate the presence of a jejunal ulcer does not exclude its presence. In the diagnosis of jejunal ulcers it is most important to realize that these ulcers may occur, as in one case proved by operation, within a month of the former operation. The longest period of good health that any patient enjoyed following a gastro-enterostomy before a proved jejunal ulcer developed was seven years.

The presence of gross or microscopic blood in the stomach contents has been an almost invariable accompaniment of jejunal ulceration in our experience. The absence of blood in the gastric contents makes the diagnosis doubtful. The presence of free hydrochloric acid in the gastric contents was demonstrated in all our cases. The presence of a tender mass at the site of the stoma, in conjunction with the foregoing symptomatology, may be regarded as pathognomonic of jejunal ulceration. There is little more than the foregoing to

Fig. 3 (Mr. R.)—Gastro-enterostomy twenty years before indigestion for the last nineteen years. Association of a duodenal ileus (A) with a jejunal ulcer (B) the ileus due to obstruction of the afferent jejunal loop due to edema and scar.

aid one in establishing the diagnosis apart from roentgen study.

It cannot be too strongly emphasized that the roentgen examination of patients suspected of harboring a jejunal ulcer should be a combination investigation by the clinician and the radiologist. We have been impressed with the increasing instances of our ability to demonstrate the presence of jejunal ulcers when the fluoroscopic examination of the patient is undertaken by the radiologist and the clinician as a team.

In going over the histories of our early cases of jejunal ulcers proved at operation there was constantly reiterated in the operative note the fact that the distal limb of the jejunum was dilated. In our later combination studies we have found this phenomenon to be almost constantly present in patients suffering from jejunal ulceration and indeed in some instances it has been the only positive roentgen finding. Our positive roentgen observations of jejunal ulcer are based on the presence of this dilated distal limb of the jejunum, plus a crater that can be demonstrated and filled with barium.

We have been impressed with the necessity of manipulation under the fluoroscope, in order to displace the overlying greater curvature of the stomach so as to make possible the visualization of the stoma (figs. 1 and 2). The use of the pressure bag with the patient lying on the abdomen has been of real value in demonstrating these ulcers. Tenderness over the stoma, we believe, is of value but must not be regarded as absolute evidence of ulcer, because we have elicited tenderness on accurate pressure over the stoma in patients who did not have jejunal ulcer. We can confirm the fact that the tender point on the abdomen corresponds accurately to the site of the ulcer, in other words, the change in level of the ulcer between the erect and the prone position is accompanied by a change in the point of maximum

tenderness on the abdominal wall. The presence of a duodenal ileus resulting from stenosis of the proximal limb of the jejunum, due either to scar or edema, is of additional diagnostic value (fig. 3).

Even the most expert and careful radiologic examination fails in some instances to prove the presence of a jejunal ulcer. In one patient operation was undertaken to close an acute perforation of a jejunal ulcer. Later roentgen studies failed to reveal a crater, but subsequent operation within a short time demonstrated the presence of the ulcer. While one may often be left with indecisive evidence after careful roentgen study, we believe that, given a suggestive history of a bizarre type of indigestion, the presence of blood and free hydrochloric acid in the gastric contents, tenderness on accurate pressure over the stoma, a dilated distal limb of the jejunum in a patient who is suffering a crippling disability, we are justified in a diagnosis of jejunal ulcer, even though we cannot demonstrate a niche or crater, and we are warranted in advising a laparotomy.

In the treatment of these patients one is astonished at the improvement in the comfort and general condition of the patient who submits to bed rest. Many of the patients who had a large tender, palpable mass at the site of the stoma will in a few weeks be perfectly comfortable, and no mass can be palpated. In such patients with a palpable mass, or roentgen evidence of penetration of the ulcer, bed rest with dietetic control for some weeks is of the utmost value. However, the disappearance of the symptoms and the improvement in the patient's general condition should not be accepted as evidence of the cure of a jejunal ulcer. In our experience the symptoms recur invariably on return to

Fig. 4 (Miss C.)—Jejunal ulcer. Resection of jejunum and stomach. Anastomosis of stomach to descending duodenum end to side. Displacement of duodenum to the left with development of duodenal ileus, relieved by subsequent Polya reconstruction.

normal, active life, and thus very recurrence of the symptoms under such conditions tends to confirm the clinical diagnosis of jejunal ulcer.

Therefore, a patient on whom a definite diagnosis of jejunal ulcer can be made should be not only advised but urged to submit to operative intervention at an early date. The frequency with which the transverse colon has been in intimate relation to the ulcer base has

impressed us. This relationship may in a short time progress to the formation of a gastrojejunal fistula.

What operative procedures are there to offer? First, the restoration of continuity of the tract by the undoing of the gastro-enterostomy and repairing the defect in the jejunum. This will be efficacious and yield brilliant results in the patients who have no demonstrable evidence of a duodenal ulcer. In three instances we have limited our operative intervention to this procedure, in the presence of a definite though apparently quiescent duodenal ulcer. In all three the clinical result has been bad, the patients suffering severely from symptoms of duodenal ulcer.

Second, the undoing of the gastro-enterostomy, the restoring of the continuity of the jejunum and then doing a local attack on the ulcer in the form of a pyloroplasty or a gastroduodenostomy. Of twenty-eight cases with primary pyloroplasty for duodenal ulcer, we have reoperated in three. In none, in subsequent roentgen studies, have we found normal gastric motion. There is a constant hyperperistalsis, and the patients have not had brilliant clinical cures. In nine cases in which

gastroduodenostomy was the primary procedure, we had one fatality and four instances of stomal ulceration. These results lead us to view with some skepticism any local procedure as a means of curing duodenal ulcer.

Third plastic operations on the gastro-enterostomy stoma, combined with an entero-enterostomy without excision of the stomach or jejunum. In early cases this technic has been invariably followed by disappointing results.

Fig 5 (Mr L. M.)—Gastrojejunal fistula which does not show with motor meal.

Fourth, undoing of the stoma, restoration of continuity of the jejunum, partial gastrectomy, and anastomosis of the stomach end-to-side of the descending limb, i. e., the second part of the duodenum. We have done four such cases and have had three instances of stomal ulceration follow and one case of severe duodenal ileus (fig 4).

Fifth, the restoration of continuity of the jejunum, combined with a partial gastrectomy and an anterior Polya anastomosis, to which is added an entero-anastomosis. This was done in one case with the development of an ulcer in the efferent loop of the gastrojejunal stoma.

Sixth, a partial gastrectomy and resection of the jejunum and restoration of continuity of the tract by an end-to-end anastomosis of jejunum to jejunum and an end-to-end anastomosis of stomach to duodenum.

Seventh, resection of stomach and jejunum with end-to-end anastomosis of the jejunum and retrocolic Polya anastomosis of stomach to jejunum.

Either the sixth or the seventh operation corrects the physiologic fault of hypermotility and hypersecre-

tion of the stomach and in our cases has been followed by a very marked and appreciable decrease in the hydrochloric acid content of the stomach, in fact, in most instances by a complete absence. So far we have had no recurrence following either of these procedures, which were proved by operation. One patient has had

Fig 6 (Mr L. M.)—Showing necessity of combining barium enema with motor meal as the stomach is filled during administration of barium enema the result of a gastrojejunal fistula.

two hemorrhages two years and two and a half years after operation. We have not had an opportunity of studying this patient, either clinically or roentgenographically since this occurred, but we are prepared

Fig 7—Section of stomach from region of stomal ulcer showing marked polymorphonuclear cellular infiltration. A picture of a very definite chronic gastritis.

to believe that he may be suffering from a recurrent jejunal ulcer.

We have been impressed by the fact that the jejunal ulcer found at operation in a patient who has been given adequate preoperative treatment may be very insignificant, and for this reason we prefer, rather

than to take down the anastomosis to resect the jejunum and stomach *en bloc* and restore continuity of the jejunum by an end-to-end anastomosis, and restore gastric continuity by a Billroth I or posterior Polya technic. In several of our cases the ulcer which was present at the time of operation was so small that evidence of its presence would have been entirely destroyed had we undone the anastomosis as a preliminary procedure. Such a procedure would destroy the irrefutable evidence of a jejunal ulcer and raise a doubt as to the wisdom of proceeding with the resection of the pyloric end of the stomach. This procedure is, in addition, not only time consuming in a necessarily long operation but adds materially to the risk of infection.

In our experience, if a pyloric resection is not done and evidence of a duodenal ulcer is present, we fail to cure our patient. During the time since we have adopted this policy, resection was done in only three of our cases on the evidence outlined in which a stomal ulcer was not found, but in these the patients' indigestion was cured. In each instance there was microscopic evidence of a well marked gastritis (fig. 7). In this series there were four cases of gastric jejuno-colic fistulas. The diagnosis of such a lesion can often be made only by the giving of a barium enema. Often the barium motor meal will show no evidence of the connection with the colon (fig. 5) but after the administration of the barium enema the stomach is visualized (fig. 6). We have had one operative death. This was due to a failure on our part to recognize the fact that there could be a tremendous accumulation of content in the resected stomach, proximal jejunum and duodenum without the patient complaining of nausea or vomiting, and compatible with a normal temperature and pulse rate. In this instance the proximal jejunum and duodenum were dilated until they held more than 3 quarts (liters) of fluid, and the patient died from peritonitis as the result of a giving way of our end-to-end suture of jejunum to jejunum. Since this time we have left a duodenal tube in the stomach as a routine following gastric operations until such a time as the edema about the stoma permitted normal emptying of gastric contents. In the other three instances of gastrojejuno-colic fistula we had two brilliant results, in which we did a massive resection of colon, jejunum and stomach *en bloc*, with an uneventful convalescence. In the final case we contented ourselves with undoing the anastomotic ulcer from the colon and repairing the defect in the colon. This patient recovered, but only after the development of a local peritonitis and a sub-phrenic abscess. We thus at the moment believe that a massive resection of stomach, jejunum and colon *en bloc* with a triple anastomosis and a cecostomy is the ideal procedure. This, if supported by combination anesthesia and blood transfusion before, during and after the operation, is not too forbidding a procedure.

CONCLUSIONS

1 A careful and exhaustive follow up of patients who have been submitted to a gastro-enterostomy shows a much higher incidence of jejunal ulceration than is usually suspected.

2 A persistent gastro-intestinal disability in a patient who has had a gastrojejunostomy demands a careful and thorough investigation.

3 Roentgen investigation of such patients is more efficient if the clinician and radiologist cooperate as a team.

4 Jejunal ulceration is a surgical lesion, and operation should be urged as soon as the patient's condition permits, provided the diagnosis is thoroughly substantiated.

5 Block resection of the stomach and jejunum, with end-to-end anastomosis of the jejunum, and either a Billroth I or retrocolic Polya reconstruction of gastric continuity is the ideal procedure.

6 A barium enema should be a routine procedure in the investigation of any patient suffering a gastro-intestinal disability after a gastro-enterostomy.

7 The ideal operation for a gastrojejuno-colic fistula is a block resection of stomach, jejunum and colon, with triple anastomoses, together with a cecostomy.

170 St. George Street

ABSTRACT OF DISCUSSION

DR. DEAN LEWIS, Baltimore. The authors have done a distinct service by indicating the necessity of cooperation between the roentgenologist, the surgeon and the internist. More information is obtained by direct examination than by questionnaires. There is a great variation in the incidence of gastrojejunal ulcer and jejunal ulcer following gastro-enterostomy. Some surgeons report 1 per cent, some 2 per cent and some 35 per cent. The only constant factor behind these figures is the surgeon. I do not know how to explain this, but experimentally one can reproduce gastrojejunal ulcer by poor suturing and I think that has been done repeatedly at the operating table. In performing a gastro-enterostomy, I always prepare the field for the man who follows me, making it easier for him to do the second gastro-enterostomy. This is most easily done by suturing the mesocolon high up on the stomach wall so that the line of suture is immediately exposed at the second laparotomy. Some sutures are extremely bad in stomach work, and I refer particularly to the continuous mattress suture. When the continuous mattress suture is inserted part of the stomach wall will slough. It must of necessity slough because it is strangulated. This not infrequently is the basis of gastrojejunal ulcer. I believe that the best suture for stomach work is the one devised years ago and forgotten but recently revived. This is the suture that Billroth originally used. It is a three-layer suture and it accurately approximates the mucous membrane. With such a suture there is much less chance of loss of tissue strangulation or subsequent death through peritonitis and less possibility of forming a new ulcer. A year ago Dr. Gaither examined 100 cases in Baltimore which had been accurately observed and questions carefully put and found almost 89 per cent recoveries from gastro-enterostomy. The authors also spoke of jejunal ulcers, which develop distal to the stomach. He is perfectly right when he states that the cases with high acidity and hyperactivity of the stomach have to be carefully considered and the type of operation carefully selected. I am quite certain of one thing. I would not want the greater half of my stomach resected to cure a duodenal ulcer because it might recur in the portion left behind.

DR. ROSCOE R. GRAHAM, Toronto. I should like to stress the point that a very small number of individuals who harbor duodenal ulcers should be candidates for surgical therapy. Secondly, the patient who has had a gastro-enterostomy and complains of symptoms is entitled to a thorough painstaking investigation in which the clinician, the internist and the roentgenologist act as a team.

The Large Intestine—In the large intestine the digestive juices continue to act upon the remnants of the foodstuffs and a further absorption of the products of digestion takes place. The progress of the food material through the large intestine takes a comparatively long time (often eighteen hours or longer) during which there is a marked absorption of water and the residual material gradually becomes more solid.—Sherman H. C. Food and Health New York, Macmillan Company, 1934.

CALCINOSIS CIRCUMSCRIPTA

REPORT OF CASE

GALE WILSON, M.D.

SEATTLE

According to Barr,¹ "calcinosis" is the term used to describe a deposit of calcium in or under the skin. It has also been applied to more or less scattered deposits in the subcutaneous tissues.

'Calcinosis circumscripta' is a condition in which calcification is limited to the skin. It occurs almost always in the upper extremities, especially in the fingers, and interferes little with the general health of the patient.

Careful history usually reveals that the patients have suffered from cold hands since early childhood and that the calcium deposits have occurred gradually.

This condition was apparently first reported about 1855, and since then there have been many cases reported, all stressing to some degree the relations of the blood serum calcium and phosphorus. By far the most exhaustive study of modern times is that of Barr, whose admirable definition has been given. He lists 172 references to the literature of the past eighty years. In spite of being stressed, in none of the reported cases have the blood calcium and phosphorus values been especially indicative or abnormal and Barr and Thannhauser² are in accord in discarding the idea of a generalized calcium disturbance and in considering the process to be the expression of a locally damaged tissue, especially following the nutritional defects of Raynaud's disease or scleroderma. Hence the process becomes one of dystrophic calcification.

It has been known before³ that in addition to the local nutritional factors there are certain systemic conditions which enhance the local deposition of calcium. Among these factors may be mentioned the pH of the blood, the action of sunlight and the ingestion of vitamin D with the action of parathyroid extract not to be overlooked. The action of sunlight and that of vitamin D are to be especially noted here, because of the peculiar blood chemistry of the case under consideration, i.e., an unusually high blood cholesterol, which may well have been the source of a "poisoning with endogenous irradiated ergosterol".⁴

REPORT OF CASE

History—Mrs J F B aged 63 seen Dec 19, 1932 had always been well and healthy. About ten years before, while living in Seattle she began to notice occasional spells of blanching and numbness of the fingers of both hands, the attack lasting three or four hours from beginning to end. She consulted a physician who told her that she had Raynaud's disease and that nothing could be done about it. About three years later the intermittent claudication disappeared spontaneously and for a period of about two years she had no further trouble with her hands. About five years before I saw her (also about five years after the claudication first began) she noticed a slowly increasing swelling of the tips of the right thumb and forefinger. This swelling had persisted without remission for the past five years getting rather more painful the more she used her hands but unaffected by the ordinary ranges of temperature. During unusually cold weather the finger tips got bluish and somewhat numb but not as much

so as they did ten years before. About six months after the first swelling of the thumb several small, pinhead-like white spots appeared on the flexor surface of the distal joint of the right thumb. These spots were not tender except on deep pressure, slowly enlarged until about 3 mm in diameter, and then came to the surface and were discharged, either spontaneously or after the overlying skin which had thinned out to tissue paper thickness had been pricked. The discharged material was chalky, gritty to the touch, and sometimes thinner and more purulent appearing than at other times. Healing always took place within a few days.

About four years before I saw her the left thumb and forefinger became similarly involved, but the nodules had never been as numerous or expelled so rapidly as on the right hand, where one or more spots would mature and be expelled every two or three weeks. Within the past year and a half the middle fingers of each hand had shown a few similar spots.

The past history was negative for any serious illness. The family history was entirely negative especially for gouty or other metabolic diseases. The patient had been married for forty years and had two grown children.

Examination—At the time of the first visit the patient was a well developed and nourished woman. She looked considerably younger than her given age of 63. She was rather nervous, intelligent and cooperative. The head, neck, eyes, ears, mouth and throat were normal. There were no tophi or abnormal deposits. The chest was rather flattened anteroposteriorly. The breasts were atrophic. The heart was normal in size, rate and rhythm. There were no murmurs. The pulse was 88. The blood pressure was 110 systolic, 80 diastolic. The abdomen was normal. The hips and thighs were unusually wide in proportion to the general build, and there was a very suggestive deposit of fat over the outer surface of the thigh, almost amounting to a true 'breeches'. The ankle and foot were disproportionately small. There were slight hypertrophic changes in the patella. The hands showed clubbing of the tips of the thumbs and forefingers with all the other fingers tapering normally. Both thumbs and both forefingers were about one fourth larger than the other fingers, and each presented from the distal interphalangeal crease to the tip from a half dozen to twenty hard grayish white, pearly bodies varying in size from the head of a small pin to 4 mm, all apparently lying within the skin itself, the smaller ones being the most deeply placed. There was no elevation of the nodules, the skin over the largest ones being reduced to tissue paper thinness. On squeezing the right thumb between one's fingers there was a gritty sensation exactly like that felt on squeezing a tightly filled sand bag.

The laboratory report at the time of the first visit was not remarkable: hemoglobin, 69 per cent, red blood cells 3,840,000, white blood cells 10,300 with a differential count of polymorphonuclears 67 per cent, lymphocytes 31 per cent and monocytes 2 per cent. The urine was entirely normal except for a slight trace of albumin. The stool was entirely normal. The basal metabolic rate was 0.

One large nodule was excised, and it was found to extend entirely through the thickness of the skin but not into the subcutaneous tissue. On section a thick, grayish white chalky material was evacuated. A smear of this material showed only a few pus cells among nontypical amorphous crystals.

Progress—Jan 11 1933, a dextrose tolerance test was done and the following unusual values were obtained:

Hour	Sugar Mg	Cal cium Mg	Phos phorus Mg	Choles terol	Lecithin	
Fasting	85.5	9.8	3.4	411.5	0.0	
1 hour	131.6	10.9	3.0	444.5	0.0	
2 hours	117.6	10.0	2.8	444.4	0.0	
3 hours	90.0	9.6	2.6	470.0	0.0	Urea 13.2
4 hours	74.1	10.0	2.6	468.0	0.0	Uric acid 4.0

A roentgenogram taken of the right hand at this time showed the peculiar condition shown in figure 1.

Because of the very unusual blood chemistry as regards cholesterol and lecithin in spite of a negative gallbladder history, an oral cholecystogram was done. There was slight filling of the gallbladder with the dye.

January 23 the fingers were unchanged. Another spot was breaking through on the right thumb and incision of this spot yielded a chalky, gritty material, which was insoluble in ether, chloroform, acetone or alcohol but which did dissolve on standing over night in dilute nitric acid. Chemical analysis of the dissolved material showed the presence of calcium and phosphorus with a very small amount of organic material. The patient was empirically put on a purine-free low fat diet and

Fig 1—Appearance of fingers Jan 11 1933 most used portions involved

given desiccated thyroid one-half grain (0.03 Gm) three times a day with tablets containing bile salts.

February 3 the patient felt drowsy and listless, the fingers were cold to the touch and somewhat blanched. Three days later another spot opened up and discharged, this time evacuating a cheesy material. At this later date the blood cholesterol had fallen to 220 mg per hundred cubic centimeters, and two weeks later (February 24) it had fallen to 188 mg.

March 21 the patient returned from a two weeks' visit into central Idaho where she encountered subzero weather and had several attacks of real claudication. On arrival here she felt better but the fingers tended to remain cold and more spots appeared.

April 10 the blood cholesterol was down to 180 mg and the lecithin, which could not even be detected in January, had risen to 11.6 mg on February 7 and to 14.2 mg in April, but the right thumb was definitely more swollen and tender, and several nodules were maturing at once.

The latter part of April the blood uric acid was 4.4 mg per hundred cubic centimeters and the diagnosis once more leaned toward an atypical gouty condition. Under treatment with cinchophen 10 grains (0.65 Gm) three times a day the uric acid was reduced to 3.6 mg within three days, but with no change in the fingers.

May 12 another dextrose tolerance test was done, this one showing perfectly normal figures for cholesterol, lecithin, sugar, calcium, phosphorus and uric acid. The basal metabolic rate had been increased to plus 12 per cent by the thyroid.

At the conclusion of this test the patient was given 2 cc. of "Tissue Extract" (S & D) and promptly fainted. She recovered rapidly and returned three days later stating that she had not noticed any vasomotor effect whatever from the injection. She was given 25 cc. more of the tissue extract and fainted again, perspired profusely and remained listless and weak for two days, but without appreciable change in blood pressure or any sign of peripheral vasodilation.

May 24 the thyroid was increased to 2 grains (0.13 Gm) a day. June 16 she reported for another blood check up and this time showed a cholesterol of 130 mg, calcium of 12 mg, lecithin 11 mg and uric acid 3.9 mg. At this time parathyroid gland one-tenth grain (0.006 Gm) twice a day, was added to the regimen plus an increased water intake. Also another nodule was incised, again extending down to, but not into, the

subcutaneous tissue. Four days later another spot was removed from the right thumb, and in ten days there was a whitish pin-point spot in the depth of the healing scar. When this spot showed in the healing area, salicylic acid (10 per cent) in collodion was applied, only to have an adjacent, untreated area near the tip of the thumb become tender and peel off, leaving the salicylic acid treated area untouched.

July 28 the calcium had dropped to 11 mg and the phosphorus was at its old level of 3.3 mg per hundred cubic centimeters. August 21 the blood cholesterol was 140 mg per hundred cubic centimeters.

COMMENT

Here was an elderly woman who had chalky deposits in the tips of the fingers she used most. She had an increased density of the costal cartilages on roentgen examination and one or two small pinheads of calcium in the heel, but was otherwise in apparently normal health. At first glance it would seem to be podagra, but the blood uric acid was not sufficiently elevated, and the "pearls" in the fingers were too opaque to X-rays, being practically as dense as the bone itself. Xanthomatosis had to be considered but there was no demonstrable tendon involvement even with the high blood cholesterol and no fatty substances could be detected in the material removed from the nodules themselves. The fatty deposit over the thighs and hips was suggestive of a pituitary disturbance, possibly progressive lipodystrophy, but that did not account for the blood changes or for the local deposits. The opacity of the deposits showed the presence of calcium salts, and chemically the nodules contained nothing in measurable quantity except calcium and phosphates. With a definite history of intermittent claudication of many years' duration, even with many years' remission before the local deposits were first noticed, one must admit some degree

Fig 2—Same hand Jan 11 1934 slight increase in deposits.

of local nutritional change in the fingers, but in this particular case it would seem, in view of present knowledge of the effects of ultraviolet radiation on cholesterol and ergosterol, that the unusually high cholesterol in the blood stream could bring about an endogenous "hypervitaminosis D," which would cause the calcium to deposit in the soft tissues of the abused finger tips.

During the course of treatment the blood cholesterol has been reduced to normal and the lecithin increased from an immeasurably small amount to normal, but there has been no improvement in the fingers other than a possible slight slowing of the rate at which the nodules mature and discharge.

Smith and Elvove⁵ experimenting with viosterol poisoning, found that a high serum phosphate with a normal or slightly increased serum calcium resulted in great calcification of the soft tissues, whereas no abnormal deposition of calcium was found when the serum phosphate values were low. The case under consideration showed serum calcium and phosphorus values that were always well within the normal limits.

Rabl⁶ and Kleimann⁷ experimented with changes in the acid-base equilibrium and found marked changes in the renal excretion of calcium and phosphorus but apparently little change in the much larger quantity lost through the large bowel. In the present case I have repeatedly tried alkalinizing the patient over long periods of time and then putting on a high protein acid-forming diet, but without noticeable effect. Kleimann has also shown that the dystrophic deposition of calcium in the tissues begins about a minute crystal of tertiary calcium phosphate, and once formed they readily extract more calcium phosphate from the blood stream (or even from the spinal fluid) and continue to grow. The real question, however, is what to do to give relief to the patient, or how to remove the deposits without removing the finger tips with them.

SUMMARY

A typical case of calcinosis circumscripta was studied, with extensive blood chemistry and clinical observations over a period of one year. The blood chemistry tends to show that the deposits of calcium phosphate in the fingers may be due to an endogenous hypervitaminosis D caused by an unusually high blood cholesterol (480 mg per hundred cubic centimeters) superimposed on an old remitted Raynaud's disease. All types of eliminatives have been tried as well as changes in the acid-base ratios, high protein low protein, fat free, purine free and other diets, all without doing other than slightly slowing up the rate of maturity of the nodules, even after the blood chemistry had been restored to normal.

The First Five Weeks of Development—In the first five weeks of human development changes take place very rapidly. In that short time the fertilized ovum passes from the condition of a single cell with a diameter of about $\frac{1}{200}$ of an inch to a fully formed human embryo about $\frac{1}{2}$ of an inch in length (5 mm) and contained within a spherical envelope of embryonal membranes which measures nearly an inch in diameter. By the end of the fifth week the beginnings of all the parts of the adult body are recognizable—the head, the trunk, the limb buds, the primitive segments, the eyes, the nose and mouth. A section across the abdominal cavity of an embryo at this stage reveals the fact that the foundations of the genital glands are already laid and that certain cells have been set aside for the reproduction of another generation.—Keith Sir Arthur. *Human Embryology and Morphology*, Baltimore, William Wood & Co 1933.

About fifty cases of congenital heart block have been reported in the literature. Several authors have collected and analyzed the reported cases. There is some difference of opinion concerning the correctness of the diagnosis in a few of them, as in some there was no graphic proof that heart block actually existed and in others there was considerable doubt that it was congenital and not acquired. The heart rate of an infant is normally very rapid and in the presence of a partial block or even of a complete block the rate, though relatively slow in comparison with the normal for the age, may still be faster than the normal rate for adults. Hence the presence of an interference with conduction may easily be overlooked. Until recently, when medical men began to become aware of its possibility it was rare that any abnormality of this nature was discovered within the first few weeks or months of life and sometimes years elapsed before the condition was recognized. When there is no record of the heart rate in early life, one must rely on a history of fainting spells or attacks of blueness or of dyspnea occurring at an early age before any rheumatic or diphtheritic infections have occurred.

The commonest associated anatomic diagnosis is a defect in the interventricular septum. In those cases which have come to autopsy and in which serial sections of the conducting system have been made, it has been found that the auriculoventricular bundle usually ends in a band of fibrous tissue situated about the septal defect. Yater, Lyon and McNabb¹ in 1933 reviewed the literature up to that time and in 1934 Yater, Leaman and Cornell² analyzed those cases in which serial sections of the conducting system had been made at autopsy.

We present here another case in which the diagnosis of heart block is certain and undoubtedly congenital in origin and which is associated with a structural lesion in the heart probably congenital.

REPORT OF CASE

History—A boy born in 1927, was admitted to the Louisville City Hospital on Oct. 13 1932 being referred by the tuberculosis clinic because the mother stated that the child had had attacks of dyspnea and cyanosis since he was an infant.

He was the third child the previous two being normal but a subsequent baby was found dead in its crib at the age of 2 months. The mother had constant hemorrhages during the last month of pregnancy, but delivery was normal at full term. The baby weighed 8½ pounds (3,855 Gm) at birth. He breathed and cried at once and was not a blue baby. When

FIG 1—Outline of heart July 6 1934 at a distance of 7 feet with the patient standing showing a prominence in the region of the left auricle or slightly above in the pulmonary region. Measurements are distance to right border 3 cm to left border 7.1 cm total transverse diameter of heart 10.1 cm maximum internal diameter of chest 21.5 cm.

From the Departments of Medicine and Pediatrics of the University of Louisville School of Medicine.

1 Yater W M Lyon J A and McNabb P E. *Congenital Heart Block*, J A M A 100: 1831 (June 10) 1933.

2 Yater W M Leaman W G and Cornell V H. *Congenital Heart Block*, J A M A 102: 1660 (May 19) 1934.

only a few weeks of age he had a sudden attack of dyspnea and blueness. Since that time he had had similar attacks once or twice a month. During these attacks the mother could not keep him covered because he always climbed up on the pillows to get his breath. At times his mother would find him lying in bed apparently lifeless and would awaken him to make sure he was still alive. He had never played very actively but had been content to sit by and watch the other children play.

About one week before admission to the hospital and again three days later, he had an attack of fainting with loss of consciousness—the only ones in his life.

Fig 2—Electrocardiogram taken Oct 14 1932 showing complete auriculoventricular dissociation with auricular rate 109 and ventricular rate 61. Note that T_1 and T_2 are upright and T_3 inverted. There is left axis deviation.

In infancy he had whooping cough. He had colds every winter. His tonsils were removed at $2\frac{1}{2}$ years of age and he had no sore throats thereafter. He had had no other infectious diseases. At the age of 2 he fell and injured his head, being unconscious for several minutes. He was admitted to the Louisville City Hospital, where no fracture of the skull was made out. About ten days later he was circumcised, with a normal convalescence.

No record of the heart rate is available until at the time of the head injury, when it was reported as "rate 45. Normal size and shape (by percussion)." However at the time of the circumcision it was recorded as 96, and this note was made concerning examination of the heart: "Normal size rate and rhythm. There is a harsh systolic murmur heard best over the fourth left interspace just inside the nipple line but it is transmitted to the entire precordium."

Examination—The boy was somewhat small for his age and rather pale, but otherwise he appeared normal. He was not dyspneic at rest, while sitting or on walking. There was no cyanosis. The blood pressure was 118 systolic, 54 diastolic. The liver was 4 cm below the costal margin in the mid-clavicular line. There were no other signs of heart failure. Examination of the heart showed no thrill but rather loud sounds throughout with no especial accentuation and a moderately loud, only slightly harsh systolic murmur heard best just inside the nipple in the fourth interspace, it was heard also along the left border of the sternum, yet it was definitely less loud there than at the apex and it decreased in intensity as the clavicle was approached, though it could be heard over the clavicle and also at the angle of the left scapula in the back. No diastolic murmur was heard.

Roentgen examination (fig 1) showed slight cardiac enlargement and some relative widening of the left auricle.

An electrocardiogram (fig 2), October 14 showed complete auriculoventricular dissociation, the auricular rate being 109 and the ventricular rate 61. There was moderate left axis deviation and inversion of the T wave in lead 3, the P waves were not exaggerated.

The blood Wassermann reaction was negative. The red blood count was 4,040,000 hemoglobin 70 per cent (Sahli) white blood count, 8,100.

During this hospital stay, the pulse varied between 48 and 82, averaging 54 to 66.

Subsequent Course—Since October 1932 the patient has been seen several times, sometimes in the outpatient clinic, sometimes in the ward. He has meanwhile had many recurrences of the fainting spells, with loss of consciousness, dyspnea and cyanosis, the spells seem to have been induced by eating or by exertion. He has never been seen by a physician during one of these spells, but on Aug 25, 1933, Dr. Nicholson saw him during the recovery stage of one. His report was "Well until 8 p. m., while going to bed he became unconscious for five or ten minutes. This attack was repeated half an hour or so later and I saw him shortly after. He was conscious but completely exhausted, the pulse was 40, full and regular. There was no cyanosis, but he was very pale and the skin was clammy and moist." He has had occasional respiratory infections, during which dyspnea and cyanosis are more easily produced. At one time the effect of atropine on the heart block was tried, after 0.5 mg of atropine five times daily for four days, no effect on the block could be demonstrated. During the period of observation his pulse rate has remained between 48 and 70 and further electrocardiograms have shown no change in the block, complete heart block always being present. However, an interesting change in the form of the T waves did occur on one occasion. In a record made on Aug 8, 1933, T_1 , which had previously been normally upright, became quite deeply inverted, T_2 became somewhat flattened and T_3 , which had always been definitely inverted, became upright and tremendously exaggerated (fig 3). A subsequent record made Oct 24, 1933, showed a return of the T waves to their previous levels. No known change in the patient's health occurred at this time, so that the explanation of the change must remain uncertain.

COMMENT

The diagnosis of heart block is, of course, proved. There can be little doubt that it is congenital, in view of the history dating back to a few weeks from birth when he had attacks of blueness and dyspnea without any previous acute infections.

As to the anatomic diagnosis there is some uncertainty. The only murmur ever heard has been systolic in time and has always had an element of harshness in it. But the place of its maximum intensity has seemed to vary from time to time. Different observers have located its maximum intensity in different places, and even the same observers have considered this location to be different at different times, sometimes it appears loudest at the apex, sometimes in the third left inter-

Fig 3—Electrocardiogram taken Aug 8 1933 still showing complete auriculoventricular dissociation with auricular rate 112 and ventricular rate 55. Note that T_1 is inverted, T_2 flattened out and T_3 upright and tremendously exaggerated. No known change in the patient's condition occurred at this time and subsequent records have all been as in figure 2. Note also the tendency toward coupling of the auricular waves, a tendency suggested in figure 2 also and even more marked in subsequent records. Note also the change in shape of the QRS complexes in Lead 3.

space near the sternum, and sometimes in the pulmonary region just above. Most frequently it has been thought to be loudest at the apex, and this has led us to suspect a mitral lesion which, of course, would have to be considered acquired and not congenital. The presence of x-ray evidence of enlargement in the region of the left auricle lends weight to this interpretation. However, the enlargement is situated above the auricular area in the region of the pulmonary vessels, there is no diastolic

murmur, the electrocardiogram shows left rather than right axis deviation, and there is no accentuation of the P waves there is no history of an acute rheumatic infection other than sore throats, and there has been no gradual development of heart failure such as one would suspect in a mitral lesion at this age. Finally in other cases of congenital heart block the associated defect has nearly always been developmental usually a defective intraventricular septum. For these reasons we believe that the signs are to be interpreted as those of a congenital and not an acquired lesion—probably a septal defect.

Heyburn Building

CROCHET HOOK THROUGH BOTH ORBITS

W. L. BENEDICT, M.D., ROCHESTER, MINN.

A married woman, aged 55, a patient at the Rochester State Hospital, had made several attempts at suicide during depressive phases of a manic depressive psychosis. On April 1, 1934, she attempted to commit suicide by thrusting a number 12 crochet needle from the right temporal region through both orbits (fig. 1).

Fig. 1—Position of crochet hook in orbits

Fig. 2—Side view showing deflected point of hook

The sharp point of the hook entered the right temple and was pushed through the left orbit until the point struck the left temporal orbital wall. She could not push the hook farther with her hand. She removed her slipper and, using the heel as a hammer, drove the hook farther into her head until the handle was entirely buried under the skin on the right temporal side. When she was discovered a few minutes later, blood was oozing from her nose and the conjunctiva of both eyes was edematous. Her vision, however, was apparently not impaired.

On examination at the hospital the pupils were active, the eyes could be rotated normally, and examination of the fundi revealed only a few retinal hemorrhages. A roentgenogram of the head disclosed that the point of the hook had been deflected sharply on the handle about half an inch from the end and was turned backward and downward into the orbit. Obviously, it was impossible to remove the hook by withdrawing it from the right side. An incision near the temporal margin of the left orbit was made and a portion of the left temporal bony wall was removed by rongeur. The needle was then grasped with strong forceps and pulled on through in the direction in which it had been started. The bone flap was then replaced, the periosteum sutured over it and the incision in the skin closed without drainage.

The patient made an uneventful recovery without loss of vision or disturbance of ocular motility.

From the Section on Ophthalmology, the Mayo Clinic

TESTICULAR CHORIONEPITHELIOMA WITH GYNECOMASTIA AND COMPLETE PREGNANCY REACTIONS

ROBERT M. ENTWISLE, M.D., AND JOSEPH A. HEPP, M.D., PITTSBURGH

This case is made a matter of record for the reason that it is the second reported case in which the pituitary gland in a male shows the characteristic biologic and histologic changes identical with those found in the pituitary of pregnant women.

W. E., a white man aged 22, a student, was perfectly well until two and one-half months before entering St. Francis Hospital, Pittsburgh, or until four months before his death. The onset was about two months after a large shepherd dog playfully pawed him, causing some pain in the left side of the scrotum. The day following this there was some swelling in the scrotum and he consulted a physician concerning it. Within a week the swelling and pain had entirely disappeared, and from that time on the testicle gave him no concern, nor did he in any way connect this with his illness until it was brought out by questioning. Two months later he began to have pain in the back and abdomen, he noticed that he was losing weight and occasionally he had a little shooting pain in the scrotum and became very nervous. During the succeeding two months he lost strength rapidly and his chief complaints were of marked muscular weakness, shortness of breath and the abdominal and back pains as noted. Three weeks before entering the hospital he noticed for the first time a fairly large abdominal mass.

The patient was emaciated and was barely able to stand without support. He walked in a marked stooped-over position. The loss of weight had been extreme giving his eyes the appearance of exophthalmos from loss of fullness about the eye sockets. Both breasts were enlarged and tender, were slightly red, and a few drops of colostrum could be expressed from each side. There was a fairly smooth, fixed, nontender mass in the left hypochondrium, extending from the rib margin to just below the umbilicus and from slightly to the right of the midline to the flank on the left. There was a very small, hard

nontender nodule in the upper pole of the left testicle, which was about half the size of a lima bean. It was quite difficult to tell whether this was actually in the testicle or whether it was an indurated portion of the epididymis. No other masses could be palpated. There were marked secondary anemia, 1,800,000 red cells and 31 per cent hemoglobin. The Wassermann and Kahn reactions were negative. The Aschheim-Zondek test for pregnancy was positive in four separate mice. There was no cough, but roentgen examination of the lungs revealed a widespread metastatic growth.

The testicle was removed under local anesthesia, and high voltage roentgen therapy was given to the known involved areas none of which changed in appearance or size. He had a second positive Aschheim-Zondek test four weeks after the orchidectomy. He died five weeks after entering the hospital. Complete autopsy was done.¹ The removed testicle showed a very small tumor which contained layers of squamous epithelium with malignant syncytial and Langhans cells, and areas suggesting fastening villi. This multiplicity of cells, we think, establishes the diagnosis of the original tumor as a teratomatous growth. The mass in the abdomen proved to be retroperitoneal glandular tissue which was made up of syncytial and Langhans cells in typical malignant arrangement of chorionepithelioma identical with the pathologic picture found in a like tumor of the uterus. Tumor masses were also

¹ We are indebted to Dr. A. J. Bruecken of Pittsburgh for the pathologic work in this case.

found scattered throughout the lung, liver, spleen, brain, retroperitoneal nodes, kidney and suprarenal, all having exactly the same pathologic picture

The presence of hormone from the pituitary gland was demonstrated both before the removal of the testicle and afterward by the Aschheim-Zondek test. The sections of the pituitary gland showed a large preponderance of chromophobe cells and hyperplasia of basophils and a few eosinophils. These large, clear, swollen chromophobe cells are called "cells of pregnancy." We have been able to find only one other report

Fig. 1—Clear cells of pregnancy in anterior lobe of hypophysis (Notak)

of such histologic changes in the pituitary gland of a male in chorionepithelioma of the testicle

Up until June 1932 131 cases of chorionepithelioma in the male had been reported, two of these with a positive Aschheim-Zondek test. Schlagenhauer in 1902 was the first to recognize that certain tumors of the testicle were morphologically similar to chorionepithelioma of the uterus. He believed that they all were derived from teratomas. These tumors in the female begin from one or both of the double layer of trophoblast composed of syncytial and Langhans cells covering the chorionic villi and in their invasion naturally implant themselves in the uterine wall. That a teratomatous rest in the testicle

Fig. 2—Basophilic stippling of hypophysis (R. S. Ferguson)

may contain this type of cell which is the forerunner of the placenta is best explained by the theory of Delafield and Prudden. "These neoplasms are described in the older textbooks under the name cystoma or adenoma but are now suspected by many to arise from dissociated blastomeres. A blastomere is one of the cells resulting from the first few divisions of the fertilized ovum. The earliest are totipotent, since any of them can produce all the tissues of the body. Hence they differ from their descendants which become gradually multipotent or able to evolve many tissues though not

all, and finally unipotent, or capable of building but one. Teratomata of the testis are believed to arise at a time when the blastomere is totipotent, and these growths are, therefore, potentially tridermal, i. e. may contain derivatives of all three germinal layers. Now, since derivatives of all three layers are potentially present in a teratoma of the testis, the tumor, like a normal embryo, will tend to develop a chorion. Thus is explained the chorionepithelioma of the testis, a malignant and rapidly metastasizing neoplasm similar to that found in the female."

It has further been suggested to the foregoing theory that this early blastomere is a fertilized cell and that subsequently through an unknown stimulus it tends to develop as an embryo with the formation of chorionic villi.

SUMMARY

- 1 An injury to the testicle occurred two months before the beginning of loss of weight, weakness and general pains
- 2 A very small, innocent appearing tumor was produced in the testicle, with enormous metastatic growths throughout the body
- 3 The breasts were lactating

Fig. 3—Section of tumor showing Langhans cells

- 4 There was evidence of anterior pituitary activity, as proved by a positive Aschheim-Zondek test
- 5 Histologic changes in the pituitary gland were identical with those in pregnant women

It is interesting to speculate as to the part the injury by the dog had to do in the production of the condition as the history seemed quite clear as to its connection. The mere fact that such a sequence of events is frequently shown in the wildly malignant types of tumor would lead one to believe that it is perhaps more than a coincidence.

121 University Place

Ninety-Nine Per Cent of the Calcium—At least 99 per cent of the calcium and over two thirds of the phosphorus which the body contains are found in chemical combination with each other in true mineral form in the bones and teeth. The small amounts of calcium and the larger amounts of phosphorus which the soft tissues and the body fluids contain are also very important to nutrition and health. As the growing body must increase not only the amounts but also the percentages of calcium and phosphorus which it contains, it needs these two elements—and particularly calcium—in relatively greater abundance in its food than any of the other body building materials which the food supplies.—Sherman H. C. Food and Health, New York, Macmillan Company, 1934

Council on Physical Therapy

THE COUNCIL ON PHYSICAL THERAPY HAS AUTHORIZED PUBLICATION
OF THE FOLLOWING REPORTS HOWARD A. CARTER Secretary

NOTICES OF REACCEPTANCE

The Council on Physical Therapy has reaccepted the following products for a period of three years

SUNLIT ULTRAVIOLET GLASS Manufacturer Semon Bache & Company, New York City A window glass substitute which permits the transmission of a certain percentage of ultraviolet radiation This product is recommended for use in solarium

MALTESE X RAY LEAD PLATE GLASS Manufacturer Semon Bache & Company, New York City A lead glass designed for roentgen ray protective shields

BURDICK NASAL-CATHETER OXYGEN HUMIDIFIER ACCEPTABLE

The Burdick Nasal-Catheter Oxygen Humidifier is manufactured by the Burdick Corporation, Milton, Wis

The purpose of this instrument is to add moisture to oxygen while the patient is receiving oxygen therapy through a nasal catheter This form of treatment is indicated in cases of pneumonia, pulmonary edema shock following major surgical procedures postoperative pneumonia angina pectoris, asthma, and other conditions in which anoxemia or cyanosis is present The nasal catheter method of administering oxygen is simple and effective According to the firm, oxygen consumption of from 5 to 8 liters per minute will maintain an oxygen concentration at the glottis of from 50 to 60 per cent

Burdick Nasal-Catheter Oxygen Humidifier

In the nasal catheter method it is extremely important clinically to have the oxygen well humidified for the patient's throat when from 10 to 15 liters per minute is flowing

The Nasal Catheter Unit consists of a rubber hose connecting the oxygen regulating unit with the humidifier, a humidifier consisting of a wash bottle containing water, and the combined humidifier and oxygen liter flow indicator a wash bottle acting as a trap, catching any excess moisture that may be carried over from the first bottle, and a safety valve to relieve excessive pressure on the outfit if catheter or hose connections become kinked or plugged up

This unit was tested in a laboratory and clinic acceptable to the Council and was declared efficient At a flow of 5 liters per minute the Burdick Humidifier put 232 mmg of moisture into each liter of oxygen, at 10 liters 227 mmg, and at 15 liters 216 mmg

The Burdick Nasal-Catheter Oxygen Humidifier, therefore, is included in the Council's list of accepted devices

HEIDBRINK KINET-O-METER ACCEPTABLE

The Heidbrink Kinet-O Meter, a gas oxygen anesthesia apparatus is manufactured by the Heidbrink Company, Minneapolis

The unit (No 410) consists of four entirely separate and removable tank pressure regulators for controlling the contents of two tanks each of oxygen carbon dioxide nitrous oxide and ethylene Each regulator is equipped with a 3000 pound gage to register the pressure in the tanks attached thereto Each regulator has two valves for the accommodation of the tank valves Each valve is equipped with a tank stabilizer The four separate regulators are assembled into a single unit, by means of a supporting bracket that is mounted on two posts of the stand The regulators are connected to the operative head of the machine by means of high pressure rubber tubings

The operative head of the machine consists of four flow meters one each for nitrous oxide oxygen ethylene and carbon dioxide These flow meters are of the kinetic type. They are

actuated only by the flow of the gases They are without internal mechanism Registration is by means of a float and an indicating stem, the top of which indicates the amount of gases being delivered The stem rides on top of the stream of gas Each flow meter is calibrated in both gallons per hour and liters per minute These calibrations differ for the different gases Their range is as follows

Ethylene	1 to 360 gallons per hour	1/10 to 23	liters per minute
Nitrous oxide	1 to 360 gallons per hour	1/10 to 23	liters per minute
Carbon dioxide	1 to 25 gallons per hour	1/10 to 1 1/2	liters per minute
Oxygen	1 to 240 gallons per hour	1/10 to 15	liters per minute

The nitrous oxide, ethylene and oxygen flow meters are equipped with direct pressure valves by means of which large volumes of gases can be delivered instantaneously The gases are conducted separately into each flow meter They are there controlled by a needle valve mounted on top of the flow meter Manifolds connect the flow meters together and act as a channel for conducting the gases into the central chamber There is a separate manifold for the gases under regulated delivery and for the gases controlled by the direct pressure levers

Mounted on the front of the flow meter is a complete carbon dioxide absorber equipment of the closed cycle type The absorber itself is adjustable so that any amount or all of the circulation can be passed through or around the soda lime The bottom of the soda lime can is removable so that it may easily be filled and emptied when a soda lime change is required On the exhaling valve of the absorber is a lever, which operates a cam that closes the exhalation valve, thus permitting emptying the bag without removing the inhaler from the face of the patient It also enables the anesthetist to build up a definite pressure The cam lever does not, however, close the valve tightly It will open under 25 mm of pressure and therefore acts as a safety factor

There is an ether vaporizer mounted on the exhalation side of the absorber can This vaporizer is compact and adjustable It is equipped with a very dense wick to increase the amount of ether vaporization The wick is removable for replacement, cleaning and drying There is a refilling funnel on the top of the device so that ether may be poured in at any time without interrupting the anesthesia

The absorber is also equipped with a 10 quart pure gum rubber bag with a chain harness This bag can—and should—be thoroughly sterilized each time it is used There are two corrugated inhaler tubings The mask has an adjustable exhalation valve and a special shut-off valve, by means of which either air or the gas mixture can be delivered to the patient

This special valve insures that at no time will the mask ever be shut off so that the patient has nothing to breathe. A retaining strap is provided, and posts for fastening this strap to the mask are mounted on the inhaler casting

The operative head of the equipment is mounted on a telescopic post which permits raising or lowering the head of the equipment to meet variations of the operating table from the horizontal position

The entire equipment is mounted on a very stable base with four large rubber tired, ball-bearing wheels The inhaler tube and the bag are grounded to the apparatus and a special ground wire is provided with the machine, so that the apparatus itself can be grounded to a nearby water pipe

A commendable feature of the Kinet-O-Meter is that the whole machine with the exception of the soda lime tank, can be taken apart and disinfected the tank is claimed to be so caustic that no bacteria can live in it Especially important in this connection, the gas bag and face mask of this machine can be sterilized

This apparatus (No 410) was investigated in a clinic acceptable to the Council and was declared satisfactory The adver-

Heidbrink Kinet O Meter

tising matter for this product was reviewed and found to be in accordance with the Official Rules of the Council

There are other models of the Kinet-O Meter, but they are identical so far as general construction is concerned. They differ in size and capacity only.

The Heidbrink Kinet-O-Meter, therefore, is included in the Council's list of accepted devices.

Committee on Foods

THE COMMITTEE HAS AUTHORIZED PUBLICATION OF THE FOLLOWING REPORTS
RAYMOND HERTWIG Secretary

ADVERTISING DEALING WITH TREATMENT OF DISEASE OR THE NUTRITION OF THE SICK, OR RECOMMENDING ANY SPECIAL TYPE OF DIET

Advertising giving detailed instruction to the public as to methods of treatment of disease, obesity or other abnormal states is unwise and undesirable. This practice promotes self diagnosis and self treatment for which the layman is not qualified by training or experience, and thereby may endanger health or life. Special purpose diets should not be recommended to the general public. Even reducing without the advice of a physician is unwise and may be dangerous. Advertising dealing with treatment of disease or the nutrition of the sick, or recommending any special type of diet should be directed exclusively to physicians and, when not a part of medical publications, should conspicuously bear the phrase "For physicians only" or its equivalent.

NOT ACCEPTABLE

BUTTER SCOTCH CANDY 1¢ CANDYSTIX

The Curtiss Candy Company, Chicago, submitted to the Committee on Foods candy sticks called "Butter Scotch Candy 1¢ Candystix" prepared from corn syrup, sweetened condensed whole milk, sucrose sweetened condensed skim milk, coconut butter, butter, salt, butter flavor, water, glycerin, gum tragacanth, gelatin, amyl butyrate, ethyl butyrate, vanilla, butyric acid, vanillin, coumarin and caramel color.

Discussion of Name.—Butterscotch candy is a recognized confection prepared essentially from sugar, butter and molasses, and flavored with vanilla. No fat other than butter is used. Genuine butterscotch can be expected to contain from 8 to 12 per cent of butter and, of course, no coconut butter nor foreign fat nor fortification with artificial butter flavor. The composition and food values of this candy and a genuine butter scotch candy are quite different. This is an imitation butter scotch candy and should be so labeled. The name and label, therefore, are highly misleading and misinformative.

The company was advised of the recommendations of the Committee but for business reasons is not willing to change the name or label. This product therefore will not be listed among the Committee's accepted foods.

ACCEPTED FOODS

THE FOLLOWING PRODUCTS HAVE BEEN ACCEPTED BY THE COMMITTEE ON FOODS OF THE AMERICAN MEDICAL ASSOCIATION FOLLOWING ANY NECESSARY CORRECTIONS OF THE LABELS AND ADVERTISING TO CONFORM TO THE RULES AND REGULATIONS. THESE PRODUCTS ARE APPROVED FOR ADVERTISING IN THE PUBLICATIONS OF THE AMERICAN MEDICAL ASSOCIATION AND FOR GENERAL PROMULGATION TO THE PUBLIC. THEY WILL BE INCLUDED IN THE BOOK OF ACCEPTED FOODS TO BE PUBLISHED BY THE AMERICAN MEDICAL ASSOCIATION. RAYMOND HERTWIG Secretary

MELLOW PASTEURIZED HOMOGENIZED MILK

Distributor.—Superior Dairy Company, Ann Arbor, Mich.
Description.—Bottled, pasteurized, homogenized milk.

Preparation.—Milk obtained from farms licensed by the city of Ann Arbor Department of Health and under the supervision of the state of Michigan is delivered cold to the creamery, where it is pasteurized by the holding method (61 C. for thirty minutes), homogenized and filled in bottles by the usual procedure (THE JOURNAL, Sept 1, 1934, p. 681).

Analysis.—Standardized to contain not less than 4 per cent milk fat.

Calories.—0.7 per gram, 20 per ounce.

Claims of Distributor.—The cream does not separate. The curd formed in the stomach is softer than that formed from unhomogenized milk.

VICTOR MICRO-SURGICAL DIATHERMY UNIT ACCEPTABLE

Manufacturer The General Electric X-Ray Corporation, Chicago

This small diathermy unit (fig. 1) is intended for surgical use only. It is designed primarily for electric coagulation and electric desiccation but can also be used by certain specialists for straight diathermy to some parts of the body, such as the head, sinuses, ears and eyes, whenever such treatment is indicated.

This machine was investigated in a physical laboratory acceptable to the Council, which reported that it was well constructed and that the various parts were found to be firmly clamped together and assembled on an iron frame. The insulation of the wires, spark gaps, containers, and so on appeared to be satisfactory. Since the machine is designed for surgical use and will probably be used intermittently only, no temperature tests were made on the transformer. Two spark gaps have an arbitrary scale, making it possible to reproduce settings of the gap distances. In a test using salt solutions of various concentrations for a load, it was found that when the output current was about 1,500 milliamperes the power input was 142 watts. Figure 2 is a schematic diagram of the circuit.

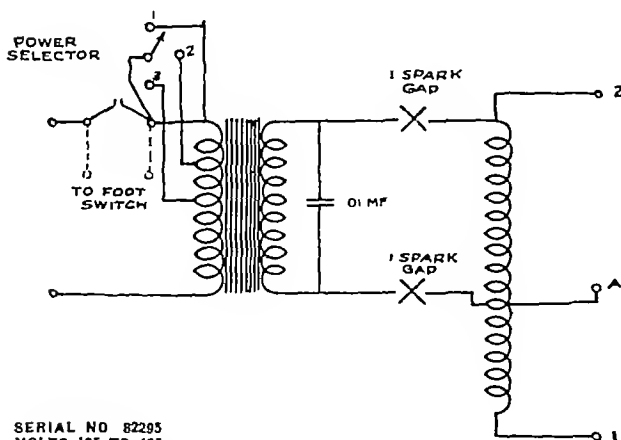

Fig. 1—Victor Micro Surgical Diathermy Unit

VICTOR MICRO-SURGICAL DIATHERMY UNIT

SERIAL NO. 82295
VOLTS 105 TO 125
FREQUENCY 50 TO 60 CYCLES
MAXIMUM AMPS 25

Fig. 2—Schematic diagram of circuit

This unit was tried out in a clinic acceptable to the Council, and the investigator reported that the machine gave satisfactory and efficient service and that the claims recorded in the advertising matter were justifiable.

The Council on Physical Therapy therefore includes the Micro-Surgical Diathermy Unit in the list of accepted devices for physical therapy.

MELLOW MILK—HOMOGENIZED, PASTEURIZED

Distributor—Affholter Brothers Creamery, Wyandotte, Mich
Description—Bottled, pasteurized, homogenized milk.

Preparation—Milk obtained from farms licensed by the Wyandotte Department of Health and under the supervision of the state of Michigan is delivered cold (16 C) to the creamery, where it is pasteurized (held at 61 C for thirty minutes), homogenized and filled in bottles by the usual procedure (THE JOURNAL, Sept 1, 1934, p 681)

Analysis—Standardized to contain not less than 3.5 per cent milk fat

Calories—0.7 per gram, 20 per ounce

Claims of Distributor—The cream does not separate. The curd formed in the stomach is softer than that from unhomogenized milk.

SUNSWET STRAINED PRUNES FOR PRUNE WHIP**SUNSWET WHIP-PRUNE (STRAINED) FOR PRUNE WHIP**

Manufacturer—California Prune and Apricot Growers Association, San Jose, Calif

Description—Strained, cooked pulp of California prunes

Manufacture—Dried prunes are thoroughly washed with hot water sprays processed for three minutes in water at 100 C surplus moisture is removed and the prunes are cooked for three hours in twice their weight of water in monel metal kettles. The prune pits are removed the flesh is passed through a copper screen, reheated, cooked to the desired consistency, filled in cleaned glass jars while still hot, processed for thirty minutes at 88 C and immediately cooled

<i>Analysis</i> (submitted by manufacturer) —	per cent
Moisture	68.6
Total solids	31.4
Ash	0.7
Fat (ether extract)	0.1
Protein (N X 6.25)	1.0
Reducing sugars as invert sugar	20.3
Sucrose (copper reduction method)	0.0
Crude fiber	0.6
Carbohydrates other than crude fiber (by difference)	29.0

Calories—1.2 per gram 34 per ounce

Claims of Manufacturer—For all table uses, also for special diets for infants and convalescents. Promotes laxation. Only warming is required for serving

UNSWEETENED COOKING CHOCOLATE

Packer—Moffat, Inc, Boston

Description—Ground cacao nibs or "chocolate liquor" in cake form. Same as Moffat Cooking Chocolate, Unsweetened (THE JOURNAL, Jan 20 1934 p 213)

Claims of Manufacturer—Conforms to the United States Department of Agriculture definition and standard.

WARRANTY SIEVED SPINACH

Manufacturer—The Nielsen Corporation, Ltd, Oakland Calif

Description—Sieved spinach prepared by efficient methods for retention in high degree of the natural mineral and vitamin values. No added sugar or salt.

Manufacture—Fresh spinach is sorted, trimmed to remove inedible portions and washed. Excess water is drained off. The spinach is inspected, heated in a steam chamber, cut and comminuted in a specially designed mill. The total time of comminuting and heating to 88 C is from ten to twenty seconds. The strained pulp is sealed in enamel lined cans and is

processed in retorts for the length of time and at the temperature specified by the California State Board of Health. The average time elapsing from the raw vegetable to the sealed can is three minutes. To avoid mineral and other nutrient losses the spinach is not blanched. The spinach comes in contact with monel metal, stainless steel or nickel only.

<i>Analysis</i> (submitted by manufacturer) —	per cent
Moisture	93.4
Total solids	6.6
Ash	1.6
Sodium chloride	0.05
Fat (ether extract)	0.4
Protein (N X 6.25)	1.8
Reducing sugars as invert sugar	0.1
Sucrose	0.3
Crude fiber	0.4
Carbohydrates other than crude fiber (by difference)	2.4

Calories—0.2 per gram 6 per ounce

Vitamins—The method of preparation and processing insures the retention in high degree of the natural vitamin values

Claims of Manufacturer—Specially intended for infants children and convalescents, and for special smooth diets. Only warming is required for serving

HAWAIIAN FINEST QUALITY PINEAPPLE

- (1) AUNT NELLIE'S CRUSHED, SLICED AND TIDBITS
- (2) JOYFUL BRAND MATCHED HALVES
- (3) KITCHEN QUEEN SLICED
- (4) RED TURKEY BRAND FANCY QUALITY SLICED (VACUUM PACKED) AND CRUSHED AND FANCY SLICED
- (5) TOM-BOY FANCY CRUSHED AND SLICED

Distributors—(1) and (3) Harrisburg Grocery Company, Harrisburg, Pa (2) and (5) Krekeler Grocer Company, St. Louis (4) J B Maltby, Inc., Corning, N Y

Packer—Hawaiian Pineapple Company, Ltd, San Francisco

Description—Canned pineapple packed in concentrated pineapple juice with added sucrose. The same as Dole Hawaiian canned pineapple products (THE JOURNAL, April 8, 1933, p 1106, and April 29, 1933, p 1338)

SUPREME BREAD SLICED

Manufacturer—Top-Notch Bakers, South Norwalk, Conn

Description—A sliced white bread made by the straight dough method (THE JOURNAL, March 12, 1932, p 889) prepared from flour, water, sucrose, skim milk powder, vegetable shortening, salt, yeast and a yeast food containing calcium sulphate, ammonium chloride sodium chloride and potassium bromate

- (1) AUNT SALLY BRAND CRYSTAL WHITE TABLE SYRUP
- (2) AUNT SALLY BRAND GOLDEN TABLE SYRUP

Distributor—Portage Wholesale Co, Portage, Wis

Packer—Union Starch and Refining Co, Granite City, Ill

Description—(1) A table syrup, corn syrup sweetened with sucrose, flavored with vanilla. The same as Union Brand Crystal White Syrup (THE JOURNAL, Sept. 3, 1932 p 833)

(2) A table syrup, corn syrup flavored with refiners' syrup. The same as Union Brand Golden Table Syrup (THE JOURNAL, July 23, 1932, p 309)

Claims of Distributor—Recommended for use as an easily digestible and readily assimilable carbohydrate supplement to milk in infant feeding and as a syrup for cooking, baking and the table.

SUN-BLEST PURE ORANGE JUICE

Distributor—Jacobson-Shealy Co Inc., San Francisco

Packer—Bireley's Hollywood, Calif

Description—Flash pasteurized California Valencia orange juice retaining in large measure the original vitamin content the same as Golden Bear California Pure Orange Juice (THE JOURNAL, Sept. 15 1934 p 839)

SPIDER POISONING

The bite of the black widow' spider (*Latrodectus mactans*) has long been recognized as poisonous to man. In spite of this recognition and of the wide distribution of the spider in the southern portion of the United States, relatively incomplete knowledge of its life history exists. Blair,¹ however, has recently reported observations based on a two year study of the spider as found in the vicinity of Tuscaloosa, Ala. It has been observed both in its natural environment and as raised in captivity.

In central Alabama the spiders are found in the angles between the roots of trees, beneath rocks around old stumps, in holes in the ground, and around houses and outbuildings. Occasionally they have been found in dark corners such as clothes closets. In general they prefer dry, dimly lighted places. Their web is distinctive, but that spun by the male is always smaller and weaker than the web of the female. The spider is capable of going without food for more than a month with no recognizable harmful effects. The food consists of insects of various sizes, but cannibalistic tastes are also evident. The common nickname "black widow" given to the female arises from her habit of capturing and feeding on the smaller male. The actual process of impregnation has not been observed but apparently occurs in the fall or early in the spring. The life span of the female is approximately one year. If hatched early in the spring the spiderling may, if the food supply is adequate, mature by late summer, live through the winter, lay its eggs the following spring and die during the summer or fall. The life span of the male is usually less than a year.

Not content with the essentially circumstantial evidence of the poisonous nature of the bite of *Latrodectus mactans* to man, Blair² submitted himself to the bite of a mature female. The resulting severe clinical reaction may be divided, he believes, into three stages. The first, that of lymphatic absorption, begins almost imme-

diately after the bite and lasted in his case about half an hour. The second stage, vascular dissemination, was characterized by severe muscular and abdominal pains, slowed, weak and thready pulse and lowered blood pressure. The temperature was at first lowered, then raised. The pulse rate also became rapid after a short time. This stage apparently lasts two or three hours. Finally, in the stage of elimination, there is a gradual return to normal.

The shock existing in the second stage may be severe. Blair believes that at this time measures should be adopted tending to a restoration of capillary tone and blood volume. Cardiac stimulants and large doses of alcohol are contraindicated. Morphine in high doses should for the same reason be used with caution. In his case immersion in a hot bath gave immediate and marked relief from pain. An acute nephritis may develop during the third stage, and attention should therefore be given to rest of the kidneys.

While limited in practical application to those regions where this spider is indigenous, the studies of Blair constitute a further step in the clarification of an interesting clinical entity.

THE EPSTEIN STATE HEALTH INSURANCE BILL

The prevention, mitigation and cure of disease in the individual human being are essentially functions of the medical profession. The people, however, have reciprocal functions, which they must exercise for the best results. These relations, under our democratic system of government, are left largely to adjustment by the doctor and his patient. When the government has intervened, it has done so only by passing laws to regulate the practice of medicine and to protect the public health. How bad a job the government has made even of this intervention is obvious from the variety of cultists and quacks that federal and state governments have licensed to prey on the people. Seldom if ever has any state, even in a single case, made a substantial inquiry into the soundness of the dogmas underlying these cults. Certainly the records of our state governments in regulating medical practice are hardly such as to encourage their entrance into new fields of medical activity.

Recently new groups, particularly social workers, have begun to manifest an active if not revolutionary interest in the nature of medical practice. While physicians have sought to cure the ills of the body and mind of the individual, the social worker has sought to cure the ills of the family and of society as a whole. While the physician has had the background of centuries to guide him, and under the law, must have professional education and training to fit him for his work and must demonstrate his fitness before he enters the medical field, the social worker need not qualify in any such manner. Any one without any education or training

¹ Blair, A. W. Life History of *Latrodectus Mactans*. Arch. Int. Med. 54: 844 (Dec.) 1934.
² Blair, A. W. Spider Poisoning. Arch. Int. Med. 54: 831 (Dec.) 1934.

whatever can style himself a social worker and engage in public activities. The social worker appears in the fields of health, economics, sociology and government without being profoundly learned in any of them. Few if any social workers are well grounded in all these fields, yet many speak with assumed authority in the whole field of social work. It is not surprising therefore that, among social workers, fads, fancies and ill regulated emotions should often guide their conduct. Yet this group, under a system now promoted by some of its leaders under the misleading appellation "health insurance," proposes to reorganize the whole practice of medicine in the United States and to make it a function of the government.

If the promoters of this system of so-called health insurance have their way, the doctor will be an agent, officer or employee of the government exactly as a teacher in the schools is such an employee. If he will submit to the conditions of employment laid down for him by some government officer or board, he may have his name registered on the list of doctors from which patients choose. Even this will obtain, however, only as long as the supervising officer or board is satisfied with his services. A government officer or board may direct his professional work. A government officer or board will pay him at rates fixed by it and subject to change without notice. The only personal privilege left to him will be the opportunity to defend himself against claims arising out of alleged malpractice, made by disgruntled government patients. What a chance he will have with such a setup! Of course the physician, like the teacher, will not have to enter the government service. He may, if he so elects, engage solely in private practice. His chances of success in such a venture however, are likely to be even less than are the chances of success of the teacher who undertakes to pursue his calling privately. Eventually, like the panel practitioners of Germany, he can choose to starve either in or out of the service. Even though an employee entitled to the supposed benefits of the health insurance scheme employs and personally pays a private doctor, the government, under the proposed scheme, goes right on collecting from him money to pay for the government medical services that he does not want.

The compulsory state health insurance law proposed by Mr Epstein of the American Association for Social Security is really an insurance bill only in name. The total losses in the group covered by the scheme are not to be distributed among those exposed to the losses in proportion to the risks. The bill would impose a special income tax on the wage of every employee within certain general classes, the amount of the tax being based on the amount of the wage and not on the medical and cash benefits proposed or on the risks to which the individual is exposed. An employee who is young, strong, in good health and in a job free from risk is to be taxed, with a few insignificant exceptions, at the same rate as are older, infirm employees in jobs that are

hazardous to health. The tax on the wages of an unmarried employee is to be at the same rate as the tax on the wages of a married employee with an invalid wife and many children, although in the former case the risk is single and in the latter case it is multiple. Moreover, the price of the so-called health insurance—or, in insurance parlance, the premium—is not to be taxed wholly against the beneficiaries of the scheme, much of it is to be collected as a special excise tax from employers, who are entitled to neither cash nor medical benefits. Employers will, of course, pass on to the public the tax they will have to pay. Then the public will be taxed further to support the scheme, for a part of the cost of the insurance premiums is to be paid directly from the public treasury. To style such a system insurance is a misnomer. It approaches more closely a system of doles than a system of insurance, for the larger part of the premium is not paid by the beneficiary. It is to be paid as a gratuity, in part by his employer and in part by the general public.

Mr Epstein's bill assumes the mental and moral incapacity of the American wage earner of today. It is the apotheosis of paternalism. If the American workman, given an adequate wage or adequate cash benefits in time of sickness cannot be trusted to provide himself and his family with adequate medical service, he must be a different American from those who brought our nation to its present high place among civilized peoples. The Epstein bill assumes that the American worker, despite his education and training, cannot be trusted to look after himself and his family and that the government must seize a part of his wages or retain a part of the benefits to which he would otherwise be entitled and with this take care of him.

In this proposal the doctor is to be just a pawn in the hands of circumstances. The opportunities afforded to him under the Epstein bill to help shape proposed policies are negligible. From the point of view of the patient, the doctor and the public health the Epstein bill is inherently vicious, un-American and antisocial. It would inevitably defeat the very purposes it hopes to accomplish.

THE PSYCHOLOGY OF MODERNISM IN LITERATURE

The American visit of Miss Gertrude Stein has caused a new focusing of interest in the peculiar aberrations of the intellect exposed by the modern literati in some of their extraordinary performances. In an editorial entitled "Pahlala and Gertrude Stein," *THE JOURNAL*¹ pointed out that Miss Stein had probably been giving demonstrations of automatic writing carried on through a dissociation of personality. In a recent address, Prof W Langdon Brown² of the University of Cambridge ventures some additional suggestions as

¹ Pahlala and Gertrude Stein editorial *J A M A* 103 1711 (Dec 1) 1934
² Brown W L We Have Reason to Think *Brit M J* 1:1 (Jan 5) 1935

to the responsibility for modernism or even "da-da-ism" in the recent output of many modern writers. He conceives, for example, that the writings of D. H. Lawrence begin with an angry reaction against the intellect and end up in literary movements which produce what is called baby talk. He asserts, moreover, that such writing communicates little to any one who does not possess the key. The inspiration wells up from the unconsciousness or at least the subconsciousness. These, however, are not intellectual processes, because the highest level of the brain selects the sensory impressions to which it will pay attention, and reason must arrange and select the messages from the emotional levels. An artist by judicial and intellectual arrangement of his material may be able to convey the thrill of his emotions. These modernists or futurists, however, endeavor to make us absorb the crude material that arises from their accomplishments without any such artistic treatment. As memories arise they create new memories and new associations, which are in most instances quite individual to the person who experiences them. Artists who include all these extraordinary manifestations of their memories do not supply us with the key, so that for many readers they speak a quite foreign language.

As an example of the type of writing which he criticizes, Dr. Brown offers the following from a poem by T. S. Eliot:

If it was to be a prize a surprise
if it was to be a surprise to realise,
if it was to be if it were to be, was it to be
What was it to be. It was to be what it was
And it was. So it was. As it was. As it is.
As it as it is. It is and as it is and as it is
And so and so as it was
Keep it in sight alright

Mr. Eliot has said that in poetry meaning only plays the part of the lump of meat in the turned up end of the dog-stealer's trousers and is merely necessary to focus the reader's attention until the poem grips him. Professor Brown's only comment on this poem is "Milton thou shouldst be living at this hour. England hath need of thee."

The tendency to link words together by sound rather than by meaning is essentially infantile. One expects babies to rhyme in this manner. One expects the insane to utter every thought that comes into their minds without worrying about continuity or sustained interest. Such writing, however, belongs in the textbooks of psychiatry rather than in essentially artistic productions of the type intended by James Joyce in "Ulysses." Man developed reason and intellect in order that he might think and express himself reasonably and intellectually. The great phrases in literature that have lived and survived the passage of time are of this character. Who, one hundred years hence, will quote Eliot or Gertrude Stein as today we quote the writings of Shakespeare, Tennyson and the Bible?

Current Comment

SPECIAL COAST TO COAST BROADCAST

Under Association News in this issue is the announcement of a special broadcast by the American Medical Association, arranged in cooperation with the National Broadcasting Company, over a coast to coast network of stations. A display announcement of the same program appears in the advertising pages in this issue. Physicians are requested to make the information about this broadcast available to their patients, and particularly to apprise them of the fact that copies of the three speeches included in the broadcast will be mailed free of charge on request to the American Medical Association, the National Broadcasting Company, or the station from which the program is heard.

HAY DIETS

In a recent issue of THE JOURNAL, Dr. Martin Rehfuess¹ concluded, after a careful study of the available observations, "There is no evidence either in the literature or in my investigation to lead me to believe that proteins and carbohydrates are incompatible in the stomach. The danger of such teaching based on a lack of scientific evidence is manifest, and while it may be true that many individuals overeat and are presumably better by a reduction of carbohydrates, the unqualified acceptance of such a teaching can lead to the occurrence of serious malnutrition as well as to a lighting of tuberculosis and old infections." It is worth while to emphasize this dictum of the gastroenterologists because many purveyors of food, restaurants, department stores and others are hallyhoing the freak diets recommended by William Howard Hay,² who urges that starches and sugars "should not be eaten with the foods known as proteins and acid fruits." For several generations, Americans have been eating meat and potatoes and drinking milk, and have as a result produced some extraordinarily healthful and powerful human beings. Indeed, nature combines proteins and carbohydrates in practically all natural food substances. As is pointed out in a recent review of some of the books on the Hay diets by Mary P. Huddleson, editor of the *Journal of the American Dietetic Association*, milk, one of nature's most perfect food substances, contains carbohydrates well balanced with protein, all vegetables, fruits and cereals contain both carbohydrates and protein. A separation of proteins and carbohydrates in the diet is actually impossible, outside of a chemical laboratory, unless one chooses to subsist largely on egg white and dextrose. Incidentally, Miss Huddleson points out that a better title for the Hay diets would be "Hay-wire diets." These diet books, in order to make the foods they recommend palatable, would torture carrots into carrot matches, splinters or horns of plenty. Hundreds of the recipes demand egg yolks, without indicating what is to happen to the rest

¹ Rehfuess, M. E. Proteins Versus the Carbohydrates. An Inquiry into Their Gastric Digestion. J. A. M. A. 103: 1600 (Nov. 24) 1934.
² A reprint of an article on Hay prepared by the Bureau of Investigation and published in THE JOURNAL Feb. 25, 1933 will be sent on request.

of the egg Simple mixtures of lettuce and other greens are promoted with such extraordinary titles as "Fountain of Youth Cocktail," "Happy Highball," "Pale Moon Cocktail," "Easter Bunny Salad," "Parcel Post Asparagus" and "Apartment Chicken." It is urged, moreover, that the use of such salads will enable the consumer to escape the devils of neurasthenia, fatigue fears, bodily distress and depressions. The promoters of "patent medicine" did much to add to the gaiety of the nation during their heyday in the public favor, but our present Hay day affords one of the most amusing spectacles ever presented to medical science.

Medical Economics

OMAHA-DOUGLAS COUNTY CENTRAL HEALTH SERVICE

The Omaha-Douglas County Medical Society made an investigation of the standards of eligibility for clinic medical care. This investigation naturally extended into programs for low income groups, and the investigating committee recommended that the county medical society establish a central health service. After a study of numerous similar experiments in other localities, the following tentative plan was recommended:

- 1 A central directing organization to be known as the Omaha-Douglas County Central Health Service, shall be established for the purpose of assisting low income patients to obtain health service at a cost they are able to pay.
- 2 The personnel of this organization shall consist of a minimum of one full time executive secretary and one field worker both of recognized standing in the field of medical social service, with necessary clerks and office headquarters.
- 3 The general policies of this organization shall be determined by a board of directors constituted as follows: three physicians, two dentists, one hospital superintendent, one nurse and one pharmacist, to be appointed by their respective professional societies.
- 4 Direction of this central health service shall be by an executive committee of three appointed by the board of directors, two of whose members shall be physicians, each member to serve a term of three years.
- 5 The Omaha-Douglas County Health Council shall act as an advisory board to this central health service.
- 6 Patients shall be referred to the central health service only by physicians or welfare agencies of recognized standing, with preliminary medical and social survey to indicate the patient's health needs and lack of resources to provide for the total cost at regular prices.
- 7 The central health service shall confer with the patient so recommended, investigate further if necessary, and recommend a percentage reduction in medical fees and costs for services needed.
8. Members of the interested organizations rendering service will be expected to indicate their willingness to accept the recommendations of the central health service in percentage reduction of rates to be charged. Such charges will be billed at regular minimum rates, with the percentage discount indicated as recommended.
- 9 Collection of all charges shall be centralized in one office with retention of 10 per cent by the central health service for operating expenses.
- 10 It shall be the obligation of the central health service to send patients who are unable to pay anything for private medical care to the teaching clinics of the city in rotation or to the county clinic if not desired for teaching purposes. Exceptions are to be made to cases of recent private status when the attending physician makes a request to continue care of the patient without charge.

Bureau of Legal Medicine and Legislation

THE PHYSICIAN'S INCOME TAX—1935

The following instructions have been prepared by the Bureau of Legal Medicine and Legislation of which Dr. William C. Woodward is Director.

The Revenue Act of 1934 under which federal income tax returns must be filed on or before March 15 next, effects numerous changes in the prior income tax law. No such change, however, relates to physicians as a class distinct from the main body of federal income taxpayers.

Every one who is required to make a federal income tax return must do so on or before March 15, unless an extension of time for filing his return has been granted. For cause shown the collector of internal revenue for the district in which the taxpayer files his return may grant such an extension on application filed with him by the taxpayer. This application must state fully the causes for the delay. Failure to make a return may subject the taxpayer to a penalty of 25 per cent of the amount of the tax due.

The normal rate of tax on residents of the United States and on all citizens of the United States regardless of their places of residence, under the Revenue Act of 1934, is 4 per cent on net income in excess of the exemptions and credits.

WHO MUST FILE RETURNS

1 Returns must be filed by every person whose gross income in 1934 was \$5,000 or more, regardless of the amount of his net income and of his marital status. If the aggregate gross income of husband and wife living together, was \$5,000 or more, they must file either a joint return or separate returns, regardless of the amounts of their joint or individual net incomes.

2 If gross income was less than \$5,000, a return must be filed (a) by every unmarried person, and by every married person not living with her husband or his wife, whose net income was \$1,000 or more, and (b) by every married person living with her husband or his wife whose net income was \$2,500 or more. If the aggregate net income of husband and wife, living together, was \$2,500 or more, each may make a return or the two may unite in a joint return.

If the status of a taxpayer so far as it affects the personal exemption or credit for dependents, changed during the year the personal exemption and credit must be apportioned, under rules and regulations prescribed by the Commissioner of Internal Revenue with the approval of the Secretary of the Treasury, in accordance with the number of months before and after such change. For the purpose of such apportionment a fractional part of a month should be disregarded unless it amounts to more than half a month, in which case it is to be considered as a month.

As a matter of courtesy only, blanks for returns are sent to taxpayers by the collectors of internal revenue without request. Failure to receive a blank does not excuse any one from making a return, the taxpayer should obtain the necessary blank from the local collector of internal revenue.

The following discussion covers only matters relating specifically to physicians. Full information concerning questions of general interest may be obtained from the official return blank and from the collectors of internal revenue.

GROSS AND NET INCOMES WHAT THEY ARE

Gross Income—A physician's gross income is the total amount of money received by him during the year for professional services, regardless of the time when the services were rendered for which the money was paid, plus such money as he has received as profits from investments and speculation and as compensation and profits from other sources.

Net Income—Certain professional expenses and the expenses of carrying on any enterprise in which the physician may be engaged for gain may be subtracted as "deductions" from the gross income to determine the net income on which the tax

is to be paid. An "exemption" is allowed, the amount depending on the taxpayer's marital status during the tax year as stated above. These matters are fully covered in the instructions on the tax return blanks.

Earned Income—In computing the normal tax, but not the surtax there may be subtracted from net income from all sources an amount equal to 10 per cent of the earned net income, except that the amount so subtracted shall in no case exceed 10 per cent of the net income from all sources. Earned income means professional fees, salaries, and wages received as compensation for personal services, as distinguished from receipts from other sources.

The first \$3,000 of a physician's net income from all sources may be regarded under the law as earned net income, whether it was or was not in fact earned within the meaning set forth in the preceding paragraph. Net income in excess of \$3,000 may not be claimed as earned unless it in fact comes within that category. No physician may claim as earned net income any income in excess of \$14,000.

DEDUCTIONS FOR PROFESSIONAL EXPENSES

A physician is entitled to deduct all current expenses necessary in carrying on his practice. The taxpayer should make no claim for the deduction of expenses unless he is prepared to prove the expenditure by competent evidence. So far as practicable, accurate itemized records should be kept of expenses and substantiating evidence should be carefully preserved. The following statement shows what such deductible expenses are and how they are to be computed.

Office Rent—Office rent is deductible. If a physician rents an office for professional purposes alone the entire rent may be deducted. If he rents a building or apartment for use as a residence as well as for office purposes he may deduct a part of the rental fairly proportionate to the amount of space used for professional purposes. If the physician occasionally sees a patient in his dwelling house or apartment he may not however deduct any part of the rent of such house or apartment as professional expense to entitle him to such a deduction he must have an office there with regular office hours. If a physician owns the building in which his office is located he cannot charge himself with rent and deduct the amount so charged.

Office Maintenance—Expenditures for office maintenance as for heating, lighting, telephone service and the services of attendants are deductible.

Supplies—Payments for supplies for professional use are deductible. Supplies may be fairly described as articles consumed in the using for instance dressings, clinical thermometers, drugs and chemicals. Professional journals may be classified as supplies and the subscription price deducted. Amounts currently expended for books, furniture and professional instruments and equipment the useful life of which is short generally less than one year may be deducted but if such articles have a more or less permanent value their purchase price is a capital expenditure and is not deductible.

Equipment—Equipment comprises property of a more or less permanent nature. It may ultimately wear out, deteriorate or become obsolete but it is not in the ordinary sense of the word consumed in the using.

The cost of equipment such as is described above, for professional use, cannot be deducted as expense in the year acquired. Examples of this class of property are automobiles, office furniture, medical surgical and laboratory equipment of more or less permanent nature and instruments and appliances constituting a part of the physician's professional outfit to be used over a considerable period of time, generally over one year. Books of more or less permanent nature are regarded as equipment and the purchase price is therefore not deductible.

Although the cost of such equipment is not deductible in the year acquired nevertheless it may be recovered through depreciation deductions taken year by year over its useful life as described below.

No hard and fast rule can be laid down as to what part of the cost of equipment is deductible each year as depreciation. The amount depends to some extent on the nature of the property and on the extent and character of its use. The

length of its useful life should be the primary consideration. The most that can be done is to suggest certain average or normal rates of depreciation for each of several classes of articles and to leave to the taxpayer the modification of the suggested rates as the circumstances of his particular case may dictate. As fair, normal or average rates of depreciation the following have been suggested: automobiles, 25 per cent a year, ordinary medical libraries, x-ray equipment, physical therapy equipment, electrical sterilizers, surgical instruments and diagnostic apparatus, 10 per cent a year, office furniture, 5 per cent a year.

The principal governing the determination of all rates of depreciation is that the total amount claimed by the taxpayer as depreciation during the life of the article, plus the salvage value of the article at the end of its useful life, shall not be greater than its purchase price, or, if purchased before March 1913 either its fair market value as of that date or its original cost whichever may be greater. The physician must in good faith use his best judgment and claim only such allowance for depreciation as the facts justify. The estimate of useful life, on which the rate of depreciation is based, should be carefully considered in his individual case.

In a Treasury Decision approved Feb. 28, 1934, No. 4422, it is held among other things, that

1. The cost to be recovered shall be charged off over the useful life of the property.

2. The reasonableness of any claim for depreciation shall be determined on the conditions known to exist at the end of the period for which the return was made.

3. Where the cost or other basis of the property has been recovered through depreciation or other allowances, no further deduction for depreciation shall be allowed.

4. The burden of proof will rest on the taxpayer to sustain the deduction claimed.

5. The deduction for depreciation in respect to any depreciable property for any taxable year shall be limited to such ratable amount as may reasonably be considered necessary to recover during the remaining life of the property the unrecovered cost or other basis.

Particular attention is called to the last of the foregoing provisions. If in prior years rates have been claimed which, if continued, will fully depreciate the cost, less salvage before the end of its useful life based on conditions now known, a reestimate of the remaining useful life should now be made and the portion of the cost that had not been depreciated at the beginning of the year 1934 (for a return for the year 1934) should be spread over this reestimated life.

Medical Dues—Dues paid to societies of a strictly professional character are deductible. Dues paid to social organizations even though their membership is limited to physicians, are personal expenses and not deductible.

Postgraduate Study—The Commissioner of Internal Revenue holds that the expense of postgraduate study is not deductible.

Traveling Expenses—Traveling expenses, including amounts paid for transportation, meals and lodging, necessarily incurred in professional visits to patients and in attending medical meetings for a professional purpose, are deductible.

Automobiles—Payment for an automobile is a payment for permanent equipment and is not deductible. The cost of operation and repair and loss through depreciation are deductible. The cost of operation and repair includes the cost of gasoline, oil, tires, insurance, repairs, garage rental (when the garage is not owned by the physician), chauffeurs' wages and the like.

Deductible loss through depreciation of an automobile is the actual diminution in value resulting from obsolescence and use and from accidental injury against which the physician is not insured. If depreciation is computed on the basis of the average loss during a series of years, the series must extend over the entire estimated life of the car, not merely over the period in which the car is in the possession of the present taxpayer.

If an automobile is used for professional and also for personal purposes—as when used by the physician partly for recreation or so used by his family—only so much of the expense as arises out of the use for professional purposes may be deducted. A physician doing an exclusive office practice

and using his car merely to go to and from his office cannot deduct depreciation or operating expenses he is regarded as using his car for his personal convenience and not as a means of gaining a livelihood

What has been said with respect to automobiles applies with equal force to horses and vehicles and the equipment incident to their use

MISCELLANEOUS

Laboratory Expenses—The deductibility of the expenses of establishing and maintaining laboratories is determined by the same principles that determine the deductibility of corresponding professional expenses. Laboratory rental and the expenses of laboratory equipment and supplies and of laboratory assistants are deductible when under corresponding circumstances they would be deductible if they related to a physician's office.

Losses by Fire or Other Causes—Loss of and damage to a physician's equipment by fire, theft or other cause, not compensated by insurance or otherwise recoverable, may be computed as a business expense and is deductible provided evidence of such loss or damage can be produced. Such loss or damage is deductible however only to the extent to which it has not been made good by repair and the cost of repair claimed as a deduction.

Insurance Premiums—Premiums paid for insurance against professional losses are deductible. This includes insurance against damages for alleged malpractice against liability for injuries by a physician's automobile while in use for professional purposes, and against loss from theft of professional equipment and damage to or loss of professional equipment by fire or otherwise. Under professional equipment is to be included any automobile belonging to the physician and used for strictly professional purposes.

Expense in Defending Malpractice Suits—Expenses incurred in the defense of a suit for malpractice are deductible as business expense.

Sale of Spectacles—Oculists who furnish spectacles, etc., may charge as income money received from such sales and deduct as an expense the cost of the article sold. Entries on the physician's account books should in such cases show charges for services separate and apart from charges for spectacles, etc.

Association News

SPECIAL MEETING OF HOUSE OF DELEGATES IN CHICAGO, FEBRUARY 15

The Speaker of the House of Delegates of the American Medical Association has issued the following official call for a special session of the House of Delegates to be held in Chicago Feb 15 1935

To the Members of the House of Delegates of the American Medical Association

In compliance with the official request of the Board of Trustees that the House of Delegates be convened in special session I as Speaker under authority of chapter III section 2 of the By-Laws hereby officially call the House of Delegates of the American Medical Association to convene in special session in the city of Chicago state of Illinois at 10 a m Central Standard Time on the fifteenth day of February 1935

The business to be transacted at this special session shall be limited to the consideration of the social and economic policies of the Association as related to pending and proposed legislation to sickness insurance and to other matters which may be submitted by the Board of Trustees

The House shall remain in session recessing from day to day until its deliberations are concluded

Signed and Issued in San Francisco California January 21 1935

FREDERICK C WARNSHUIS M D

Speaker House of Delegates American Medical Association

The meetings of the House of Delegates will be held at the Palmer House. Tentative reservations have been made at the Palmer House so that all members of the House of Delegates and all officers of the Association who are required to attend may be assured of hotel accommodations. Each delegate is urgently requested to communicate with the Palmer House, Chicago and make his own final reservation stating the kind of accommodations desired and the time of expected arrival.

By official action of the Board of Trustees, authorization has been given for the payment of necessary travel expense incurred by delegates in attending the called session of the House of Delegates in order that a truly representative meeting may be had and that no undue burden will be imposed on any delegate.

Since matters of the utmost importance to the entire medical profession are to be considered, it is earnestly hoped that every delegate who attended the Cleveland session of the Association will be present at this special session.

Section 2 chapter III, of the By-Laws of the American Medical Association, pertaining to special sessions of the House of Delegates, is as follows:

SEC 2 SPECIAL SESSIONS—Special sessions of the House of Delegates shall be called by the Speaker on written request of twenty five or more delegates representing one third or more of the constituent associations or on request of a majority of the Board of Trustees. When a special session is thus called the Secretary shall mail a notice to the last known address of each member of the last House of Delegates at least twenty days before such special session is to be held in which notice shall be specified the time and place of meeting and the items of business to be considered. No other business shall be transacted at the special session than that specified in the call.

Each delegate who served in the House of Delegates at the Cleveland session has been notified of the called meeting to be held in Chicago on February 15 in accordance with the provisions of the By-Laws, and a copy of the official call issued by the Speaker has been mailed to all delegates, as required by the By-Laws of the American Medical Association.

MEDICAL BROADCASTS

Columbia Broadcasting System

The American Medical Association broadcasts on a western network of the Columbia Broadcasting System each Thursday afternoon on the Educational Forum from 4 30 to 4 45, central standard time. The next three broadcasts will be delivered by Dr W W Bauer. The titles will be as follows:

February 7 Heart Diseases
February 14 Heart Valves
February 21 Heart Muscles

National Broadcasting Company

The American Medical Association broadcasts under the title "Your Health" on a Blue network of the National Broadcasting Company each Tuesday afternoon from 4 to 4 15, central standard time. The next three broadcasts will be as follows:

February 5 Pipes and a Pump W W Bauer M D
February 12 Rheumatism and Gout Morris Fishbein M D
February 19 Health Lessons from George Washington W W Bauer M D

Special Coast to Coast Broadcast

The American Medical Association will broadcast on a special program arranged through the courtesy of the National Broadcasting Company over a network of stations, beginning at 6 p m, eastern standard time, Monday, February 18. The program will include music and three speakers from among physicians in attendance at the Annual Congress on Medical Education and Medical Licensure, meeting in Chicago on that day. The speakers will be introduced by Dr Morris Fishbein. The speakers and their topics are as follows:

Advancement of Medical Education, Walter L Biering M D
The Prolongation of Life Ray Lyman Wilbur M D
The Battle Against Tuberculosis Kendall Emerson M D

The Only Proved Poisonous Spider—In man the bite of *Latrodectus mactans* is followed, with dramatic suddenness by a characteristic and alarmingly severe systemic reaction. The full grown female, particularly when distended with eggs appears from experiments with animals to be the most poisonous. The male, though also poisonous may, on account of its size, greater timidity and scarcity, be ignored as an etiologic factor of any importance in arachnidism. *Latrodectus mactans* is the only proved poisonous spider found in the United States—Blair, A W. Life History of *Latrodectus mactans*. *Arch Int Med* 54 844 (Dec.) 1934.

Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION, PUBLIC HEALTH, ETC.)

ALABAMA

Bill Introduced—H 87 proposes to authorize the sexual sterilization of certain socially inadequate inmates of state institutions

ARIZONA

Bill Introduced—H 19 proposes to enact a new pharmacy practice act. Apparently this bill proposes to prohibit physicians from dispensing drugs and medicines but permits them to administer personally 'drugs and medicines carried or kept for emergencies' in order to supply the immediate needs of their own patients

ARKANSAS

Bill Introduced—S 32 proposes to authorize the sexual sterilization of insane, idiot, imbecile, feeble-minded or epileptic inmates of state institutions

Bill Passed—S 35 proposing a new optometry practice act has passed the senate. The bill proposes to permit a licensed optometrist to employ any method or means other than the use of drugs, medicines or surgery for the analysis of any optical defect, deficiency or deformity, visual or muscular anomalies of the visual system to prescribe or adopt or duplicate lenses, prisms or ocular exercises for the correction, relief or need of the visual functions, or to use scientific instruments to train the visual system

DELAWARE

Bills Introduced—H 10 proposes that the property of any corporation organized for the purpose of free medical or dental aid or education shall be exempt from state, county and municipal taxes to the extent that such property is actually so used. H 23 proposes to require that before any child shall be admitted to a public school he shall present a certificate that he has been vaccinated successfully against smallpox, or a physician's certificate that vaccination is inadvisable by reason of some physical disability

DISTRICT OF COLUMBIA

Personal—John Barton Payne, chairman of the American Red Cross since 1921 died January 24 of pneumonia. Judge Payne, who would have been 80 years of age on January 26, was the son of a physician, Dr. Amos Payne.

Medical Bills in Congress—S 1016, introduced by Senator Capper, Kansas, proposes to empower the health officer of the District of Columbia to authorize the disinterment and reinterment of bodies in cases in which death has been caused by certain contagious diseases. S 1401, introduced by Senator Davis, Pennsylvania, and H. R. 4510, introduced by Representative Ellenbogen, Pennsylvania, propose to provide for needy blind persons of the District of Columbia

GEORGIA

County Society Creates Lectureship—The Fulton County Medical Society announces the establishment of the E. Bates Block Memorial Lectureship in Medicine. The lectureship was created in memory of Dr. Block by his family and will bring each year to Atlanta a prominent specialist in medicine. Dr. Foster Kennedy, New York, director of the neurologic service, Bellevue Hospital, and professor of clinical neurology at Cornell University Medical College, gave the first lecture, January 24. He discussed the relationship of neurology to medicine and the present status of psychiatry. Dr. Block, at the time of his death in October 1932, was professor of neurology and psychiatry, Emory University School of Medicine

ILLINOIS

Bill Introduced—H 47 proposes to require operators of motor vehicles to pass examinations including tests of eyesight

INDIANA

Bill Introduced—H. 66 proposes to create a board of chiropractic examiners and to regulate the practice of chiropractic. The only educational requirements to be exacted of

an applicant for a license is a high school education or its equivalent and graduation from a chiropractic college or school after completing a course of training of at least three years of eight months each. Chiropractic is defined as "the science of locating and correcting any interference with nerve transmission and expression," but licentiates are not to be permitted to practice surgery, prescribe drugs or administer anesthetics. Licentiates are also to be permitted to use the title "Dr.," provided "such designation is used in such manner as to indicate that the licensee is a chiropractor."

IOWA

Personal—Dr. Leonard A. West, flight surgeon in the medical reserve corps, has been appointed medical examiner for the bureau of air commerce in Des Moines.—Dr. Anton R. Schier has been named superintendent of the Hospital for Epileptics and School for Feeble-minded, Woodward, succeeding the late Dr. Mathew N. Voldeng. Dr. Schier was formerly assistant superintendent of the Institution for Feeble-minded Children at Glenwood.

Gavel Presented to Society—A hand carved gavel from the island of Cavaat was presented to the Linn County Medical Society recently by Dr. Arthur W. Erskine, Cedar Rapids. On the head of the gavel there is a likeness of the staff of Aesculapius with a snake wound around it. Dr. Erskine had the gavel made from native ashwood obtained from the island, which is said to be the birthplace of Aesculapius and which in ancient times was known as Epidaurus.

MASSACHUSETTS

Bills Introduced—H 1105 proposes to prohibit an insurance company, if it has actual notice that an injured insured person is indebted for hospitalization made necessary as a result of personal injuries from settling a claim for damages for such personal injuries before such indebtedness is paid. H 1276 proposes to make it unlawful for any physician or hospital in any way to influence any person, injured by accident, in the selection or retention of any attorney to prosecute or handle his claim for damages. H 1109 proposes to give to physicians, nurses and hospitals, treating persons injured through the negligence of others, liens on any judgment or settlements accruing to the injured persons on account of their injuries. H 1113, apparently to supplement the workmen's compensation act, proposes that any injury or illness accruing to a workman who has been employed twenty or more years continuously by a corporation shall be deemed to be a compensable injury or illness. S 74 proposes to authorize a divorce if either spouse has been confined in a hospital for the insane for at least five years. S 308 proposes to authorize the establishment and maintenance, in the western part of the commonwealth, of a hospital for the treatment of cancer. S 312, to enact a new chiroprody practice act, proposes to define chiroprody or podiatry as the examination, diagnosis and treatment externally by medical, mechanical or surgical means or manipulation, or by the various modalities of physical therapy, of the structures and diseases of the human foot and leg, without the use of other than local anesthetics and not including the amputation of toes or of a foot. H 1458 proposes to create a board of magnetic healer examiners and registration and to regulate the practice of magnetic healing, which the bill defines as "the science of reviving and producing life and circulation in the nerve system and cells, so as to heal all nerve affections." Apparently, no educational requirements whatever are to be exacted of applicants for licenses to practice magnetic healing. Such applicants are to be required to submit to an examination as to his or her qualifications for the practice of magnetic healing, which examination shall include the subject of nerves. H 1285, to amend the workmen's compensation act, proposes that whenever an employee claims compensation for an occupational disease his claim shall be submitted by the industrial accident board to three referees, selected by the board from a list of licensed physicians skilled in the diagnosis and treatment of occupational diseases, which list is to be prepared by the board of registration in medicine. After investigation, the referees are to report their findings of medical fact to the industrial accident board. S 268 proposes to amend the law which authorizes the department of labor and industries to require a physician, treating a patient whom he believes to be suffering from any ailment or disease contracted from any employment, to report that fact to the department, by making it mandatory for the department to pay a reporting physician 50 cents for each such report submitted and by providing that such report shall not be subject to summons nor shall its contents be made public. H 1284 to amend the workmen's com

pensation act, proposes in effect, to make all occupational diseases compensable. H 1615 proposes to accord to physicians and hospitals liens on the proceeds of any health, accident and liability insurance policy that may be due to any patient treated by the physician or hospital.

MINNESOTA

Bill Introduced—S 112, to amend the workmen's compensation act, proposes, in effect, to make compensable all diseases and infections naturally resulting from any employment covered by the act.

Minnesota Free of Tuberculosis in Cattle—The *Journal-Lancet* announces that Minnesota has been designated a "cattle tuberculosis free" state, attributing this achievement to the intensive campaign that has been carried on for the past fifteen years. The designation means that the disease is confined to less than 0.5 per cent of cattle in the state.

MISSOURI

Pathologic Society Organized—The Kansas City Pathologic Society was organized at a meeting Dec. 12, 1934, with Dr. William K. Trimble as president and Dr. Arthur H. Wells, secretary. The society will cooperate with the Jackson County Medical Society by having its meetings the hour preceding the weekly meetings of the county organization, except for one night a month when it will take over the regular period of the medical society meeting. The programs will be along clinical pathologic lines in an effort to attract physicians in all branches of medicine.

Bills Introduced—H 73 proposes to forbid the sale or other distribution of acetylsalicylic acid, carbolic acid or iodine except on the prescription of a licensed physician, dentist or veterinarian. H 87, to supplement the workmen's compensation act, proposes to make "occupational diseases compensable, provided the workman has been exposed to the producing cause for at least five years, two years of which has been in Missouri. The bill proposes to define an occupational disease as any physical change or impairment in health of an employee, arising independently of any wilful negligence on his part, tending to impair, restrict or totally disable him from performing his duties and arising from the particular product manufactured, or the means and methods of manufacture. H 133 proposes to require that all drugs and chemicals in whole or in part of coal tar origin, intended for human medication shall except when prescribed by a licensed physician be plainly labeled with their true English names and as being of coal tar origin. Labels must include statements of the dangerous effects and give the names of at least two antidotes. H 148 proposes to prohibit the sale or other distribution of marijuana.

MONTANA

Bill Introduced—H 9 proposes to amend the law relative to hospitals. The law now prohibits hospitals not held for private or corporate profit and hospitals that are institutions of purely public charity and that are exempted from any state county or municipal tax, by reason thereof from discriminating between the patients of regularly licensed physicians. The present law requires such hospitals to admit and care for the patients of any regularly licensed physician. This bill proposes to require such hospitals to admit and care for the patients of any reputable regularly licensed physician and practitioner of the healing art. It defines practitioner of the healing art as any person licensed by the state of Montana to practice osteopathy, chiropractic or any science recognized by the laws of the state of Montana. The present law imposes a fine of from \$500 to \$1,000 on any person, corporation or association who violates it "with intent to injure any patient or to injure the practice of any physician or surgeon." The proposed amendment would impose this fine regardless of intent.

NEW MEXICO

Bill Passed—H 16 has passed the house proposing to authorize all cities, towns and villages operating under special acts of the legislature to maintain hospitals, sanatoriums and other institutions for the care and maintenance of sick or indigent persons.

NEW YORK

Health Unit Disapproved—The Fulton County Medical Society at its annual meeting in Gloversville, Dec. 20, 1934, adopted a resolution registering its disapproval of a bi-county health unit for Fulton and Montgomery counties. It was said that the unit had no definite plan, was admitted to be an experimental procedure and was considered to be an additional step toward state medicine.

Society News—Mr. Frank Van Dyk, executive secretary, Associated Hospitals, Newark, N. J., addressed a joint meeting of the Syracuse Academy of Medicine and the Onondaga County Medical Society, January 17, on group hospitalization. Dr. William V. P. Garretson, New York, addressed the Medical Society of Westchester County, January 15, on "Allergy—A Neuro-Endocrine Interpretation." Drs. Chevalier Jackson, Philadelphia, and Arthur Q. Penta, Schenectady, addressed the Schenectady County Medical Society, January 8, on "Indications for Bronchoscopy" and "Oral Spirochetes and Associated Anaerobes in Pyorrhea and Lung Abscess, respectively."

New York City

Hospital News—Dr. Charles L. Scudder, Boston, delivered an address at a meeting of the clinical society of the New York Polychronic Medical School and Hospital, Dec. 3, 1934, on "Trends in the Treatment of Fractures." Dr. Elliott C. Cutler, Boston, spoke January 7, on "Treatment of Heart Disease by Total Thyroidectomy." Dr. Russell L. Cecil will give a lecture February 6, on "Foreign Protein Therapy." Dr. Pol N. Coryllos lectured January 12, on "Surgical Treatment of Tuberculosis."

Friday Afternoon Lectures—The spring series of Friday afternoon lectures offered by the Medical Society of the County of Kings will be as follows:

February 15, Dr. Charles A. Weymiller, Pediatric Advances of the Last Few Years.
March 1, Dr. Morris Ant. Diet as a Prescription in Treating Diseases.
March 7, Dr. Anthony W. Martin, Marine Office Management of Diseases of the Anus and Rectum.
March 15, Dr. Frederick Schroeder, Prescription Writing.
March 22, Dr. Meyer A. Rabinowitz, Role of the Stomach in the Production of Diseases.
March 29, Dr. Alfred C. Beck, Fibromyoma of the Uterus Complicating Pregnancy, Labor and the Puerperium.
April 5, Dr. Charles S. Cochrane, Practical Methods of Diagnosing Surgical Kidneys by the General Practitioner.
April 12, Dr. William H. Field, Management of Common Injuries.
April 26, Dr. John Hamilton Crawford, Mechanism and Treatment of Cardiac Edema.
May 3, Dr. Francis W. Currin, Roentgen Diagnosis of Primary Tumor of the Lung.

Society News—Drs. John L. Rice, health commissioner, and Sigismund S. Goldwater, hospital commissioner, addressed the Medical Society of the County of Kings, January 15, on "Relation of the Practicing Physician to the Health Department and The Department of Hospitals and the People of the City of New York," respectively. A symposium on cancer was presented at the meeting of the International Spanish Speaking Association of Physicians, Dentists and Pharmacists, January 18, by Drs. Eleanor S. Percival, Montreal, John F. Erdmann, New York, Charles F. Geschickter, Baltimore, and Frank H. Lahey, Boston. Dr. Jacob M. Gershberg, president for 1935, delivered an address on "The Late King Albert, President Poincaré, Professor Cajal and Madame Curie." The committee on cardiac clinics of the New York Heart Association held a scientific meeting January 22, at the New York Academy of Medicine, with Dr. Joseph Earle Moore, Baltimore, and Detlev W. Bronk, Ph.D., Philadelphia as speakers, on "Treatment of Cardiovascular Syphilis" and "Nervous Regulation of the Heart," respectively. Dr. Ralph Pemberton, Philadelphia, addressed the American Hungarian Medical Association, January 8, on "The Problem of Arthritis." Dr. John J. Westermann Jr. presented a paper on "Surgical Aspects of Bleeding Gastro-duodenal Ulcer" at a meeting of the New York Surgical Society, January 9.

NORTH CAROLINA

Bills Introduced—S 19 and H 32, the budget revenue bills, among other things, propose to levy an annual occupational tax of \$25 on practicing physicians, osteopaths, chiropractors and optometrists. Only one half of this tax, however, is to be levied on practitioners whose gross receipts from practice for the preceding year did not exceed \$1,000. Failure of a practitioner to pay this tax may result in the revocation of his license to practice. Counties, cities or towns are to be forbidden to levy an additional occupational tax.

PENNSYLVANIA

Society News—Dr. Charles F. Geschickter, Baltimore, addressed the Washington County Medical Society, January 9, on "Tumors and Hormones." Dr. Joseph H. Barach, Pittsburgh, addressed the Blair County Medical Society, Altoona, Dec. 18, 1934, on "Present-Day Conceptions of Arterial Hypertension."

Bills Introduced—H 102, to amend the workmen's compensation act, proposes to make compensable anthracosis, asthma or bursitis acquired or resulting from employment in any process involving mining. H 91, to amend the workmen's compensation act, proposes to make compensable certain occupational diseases, including poisoning by lead, mercury, phosphorus, arsenic, methanol, carbon bisulphide, naphtha, manganese dioxide, brass, zinc, benzol and nitro- and amido- derivatives of benzol also compressed air illness, radium or x-ray burns, chrome ulceration, cancers and ulcers resulting from tar, pitch, bitumen, mineral oil or paraffin, and infection or inflammation of the skin resulting from contact with oils, cutting compounds, lubricants, dusts, liquids, fumes, gases or vapors, also anthrax, silicosis and chronic miners asthma. H 44, to amend the workmen's compensation act, proposes to extend from thirty days to sixty days the period during which an employer must furnish an injured workman medical and surgical services, medicines and supplies and to raise the amount of an employer's liability for such services from \$100 to \$150. The bill proposes also to increase from thirty days to sixty days the period during which an employer must furnish necessary hospital treatment and limits the cost of such treatment to the prevailing charges for like services to other individuals.

SOUTH DAKOTA

Bills Introduced—H 16, to amend the chiropractic practice act, proposes (1) to require an applicant for a license to have a high school education or its equivalent and to be a graduate of a chartered chiropractic school requiring actual attendance for four (instead of three as the law now provides) school years of not less than eight months each, (2) to define chiropractic as the science of locating and removing any nerve interference and its effects" and as including "physical, hygienic and sanitary measures incident thereto," and (3) to remove the provision expressly prohibiting chiropractors from practicing obstetrics or treating contagious or infectious diseases. H 25, to amend the law prohibiting the possession or sale or other distribution of peyote (pellote) and "agva Americana," commonly known as mescal button, proposes that nothing in the law shall prohibit a duly ordained priest or minister from possessing and using peyote for sacramental purposes if he first obtains a permit from the attorney general.

TEXAS

Bill Introduced—H 133 proposes to forbid the sale or other distribution except by registered pharmacists or licensed physicians, of any article, drug or medicinal preparation intended for use as, or which may be used as, a contraceptive or prophylactic.

WASHINGTON

Bills Introduced—S 5 proposes to authorize the sexual sterilization of persons who may be potential parents of socially inadequate offspring. This bill seems to be one of the broadest and most radical sterilization bills ever considered by an American legislature. It defines a socially inadequate person as "one who by his or her own effort, regardless of etiology or prognosis, fails chronically, in comparison with normal persons, to maintain himself or herself as a useful member of the organized social life of the state" exempting therefrom persons whose social ineffectiveness is due to the normal exigencies of youth, old age, curable injuries and/or temporary physical or mental illnesses. A potential parent of socially inadequate offspring is defined as a person "who, regardless of his or her own physical, physiological or psychological personality, and of the nature of the germ plasm of such person's co-parent, is a potential parent at least one fourth of whose possible offspring, because of a certain inheritance from said parent of one or more inferior or degenerate physical, physiological or psychological qualities, would, on the average according to the demonstrated laws of heredity, most probably function as socially inadequate persons, or at least one half of whose possible offspring would receive from said parent and would carry in the germ plasm, but would not necessarily show in the personality, the genes or genes-complex for one or more inferior or degenerate physical, physiological or psychological qualities the appearance of which quality or qualities in the personality would cause the possessor thereof to function as a socially inadequate person under the normal environment of the state." H 5 to amend the chiropody practice act proposes to permit a licensed chiropodist to examine, diagnose or treat medically, mechanically or surgically, or by electrical and manipulative means or by bandaging and strapping, the ailments of the human foot. Chiropodists, however, are not to be permitted to amputate the toes or to perform any operation requiring the use of anesthetics other than local.

WISCONSIN

Bill Introduced—A 10 proposes to make it the duty of a physician knowing that a person visited by him has a communicable disease or has died from a communicable disease to report the fact to the local health officer, commissioner or board immediately, to quarantine the infected place and the family, if necessary, if the disease has been designated by the state board to be quarantinable, and to obtain the necessary placards and to report such quarantine to the local health officer, commissioner or board.

WYOMING

Bill Introduced—H 28 proposes to authorize the state department of health to conduct, in cooperation with local authorities or medical societies, clinics for physically handicapped and crippled children. The cost of the operation of such clinics is to be financed in part by a tax of 2 per cent on the sale of cigarets and chewing gum.

Bill Passed—H 34 has passed the house, proposing to create a board of chiropodist examiners and to regulate the practice of chiropody. Licensed chiropodists are to be permitted to examine, diagnose or treat medically, mechanically, surgically or by electrical and manipulative means, or by bandaging and strapping, the ailments of the human foot but are not to be permitted to amputate the foot or toe or remove any bone of the foot, or use any anesthetic other than local.

GENERAL

Society News—Dr Edwin G. Zabriskie, New York, was elected president of the Association for Research in Nervous and Mental Diseases at its annual meeting in New York, Dec. 27-28, 1934, and Dr Angus M. Frantz, New York, secretary.—The Southern Neuropsychiatric Association will hold its annual meeting at Memphis February 5-6, at the Hotel Peabody. Dr Giles W. Day, Galveston, Texas, is president and Dr Newdigate M. Owensby, Atlanta, secretary of the association.—A conference on slum clearance and rehousing was held in Washington, D. C., January 18-20, under the chairmanship of Mary Kingsbury Simkhovitch, New York, president of the National Public Housing Conference.—Dr Raymond W. Bradshaw, physician to Oberlin College, Oberlin, Ohio, was reelected president of the American Student Health Association at the annual session in New York, Dec. 27-28, 1934. Dr Wade MacMillan, Miami University, Oxford, Ohio, was elected vice president, and Dr Harold S. Diehl, University of Minnesota Medical School, Minneapolis, secretary.—A National Nonpartisan Committee for Ratification of the Federal Child Labor Amendment has been formed, with Charles C. Burlingham, former president of the Association of the Bar of the City of New York, as chairman. Mr Burlingham was president of the Welfare Council of New York in 1931.—The American Association for Thoracic Surgery will hold its annual session in New York, June 3-5.

The Woman's Auxiliary—The January News Letter of the Woman's Auxiliary to the American Medical Association gives accounts of its activities. The Woman's Auxiliary to the Nebraska State Medical Association has organized a bureau which arranges for physicians to address lay organizations. In Florida, the Dade County auxiliary (Miami) established a fund to aid widows and children of physicians and sponsored the sale of Christmas seals. The Michigan state auxiliary has made a special effort to be informed on legislation affecting the medical profession and to be prepared to discuss it before other organizations. The Georgia auxiliary participated in welfare projects, such as preparation and dissemination of information on maternal welfare, cancer and tuberculosis, the state president Mrs. John E. Penland, Waycross, is a member of the executive council of a new Child Welfare Council of Georgia. The Illinois auxiliary urges attention to medical legislation as part of its program for the year. Presiding officers of nearly 100 clubs attended a "public relations day" held by the auxiliary to the St. Louis Medical Society. Dr Joseph F. Bredeck, city health commissioner, made an address on "Public Health Nursing Needs." The auxiliary at Walla Walla, Wash., continued sponsorship of a series of health broadcasts begun last year which proved a popular radio feature. In the District of Columbia the activities were chiefly devoted to social service projects, assisting the Red Cross the Associated Charities and Emergency Hospital. Members in Racine County, Wisconsin have been visiting county and city institutions with a view to interesting members in them. In Oregon the woman's auxiliary of the state medical society is credited with a large share in the November defeat of the healing arts amendment to the state constitution which would have nullified the basic science law. In a campaign that

reached schools and women's organizations, the objective was dissemination of educational material concerning the issues involved

Medical Bills in Congress—Changes in Status H. J. Res. 117, the 'Emergency Relief Appropriation Act of 1935,' introduced by Representative Buchanan, Texas, has passed the House, authorizing an appropriation of \$4,000,000,000 for relief purposes. The United States Employees' Compensation Act is made applicable to employees, receiving compensation under the pending bill, who are disabled or who die from an injury sustained while in performance of duty, subject to certain conditions and limitations. H. R. 4442, the Treasury Department and Post Office Department Appropriation Bill for the fiscal year ending June 30, 1936, has been reported to the House authorizing, among other things, an appropriation of \$25,000 for special studies of and demonstration work in rural sanitation. **Bills Introduced** S. 600, introduced by Senator Hastings, Delaware, proposes to authorize the dissemination of information relating to the prevention of conception, and articles, instruments, substances, drugs and medicines designed, adapted or intended for the prevention of conception, (1) by any physician legally licensed to practice medicine, or by his direction or prescription, (2) by any druggist in filling any prescription of a licensed physician, (3) by any medical college legally chartered, or (4) by any licensed hospital or clinic, except in any state in which such use is prohibited by the law thereof. S. 1226, introduced by Senator Hayden, Arizona, proposes to prohibit the sending of unsolicited merchandise through the mails. H. R. 3645, introduced by Representative Fenerty, Pennsylvania, proposes to authorize the President to accept radium, in an amount not exceeding \$10,000,000 worth, from the Belgian government in payment of the debt owed by that country to the United States. The radium so accepted it is proposed, will be distributed to hospitals, medical clinics and medical research organizations in the United States. H. R. 3802, introduced by Representative Hobbs, Alabama, proposes to repeal the Emergency Officers Retirement Act of May 24, 1928. H. R. 4012, introduced (by request) by Representative McSwain, South Carolina, proposes to bring within the purview of the United States Employees' Compensation Act officers and enlisted men of the National Guard and the Organized Reserves who are physically injured in line of duty. H. R. 4030, introduced by Representative Beam, Illinois, proposes to amend "An Act to recognize the high public service rendered by Major Walter Reed and those associated with him in the discovery of the cause and means of transmission of yellow fever," by including therein the name of Gustaf E. Lambert. H. R. 4242, introduced by Representative Woodrum, Virginia, proposes to authorize the Reconstruction Finance Corporation to make loans to private colleges, universities and institutions of higher learning. H. R. 4315, introduced by Representative Reilly, Wisconsin, proposes to regulate the importation of milk and cream, and milk and cream products, into the United States. H. R. 4440, introduced by Representative Gambrill, Maryland, proposes to provide medical services after retirement on annuity to former employees of the United States disabled by injuries sustained in the performance of their duties. H. R. 4539 introduced by Representative Mead, New York, proposes to alleviate the hazards of old age, unemployment, illness and dependence, to establish a social insurance board in the Department of Labor, and to raise revenue.

Government Services

Annual Report of the Public Health Service

For the calendar year 1933 the general death rate in the United States was 10.5 per thousand of population as estimated on statistics received from twenty-seven states, the annual report of the U. S. Public Health Service reveals. This is the lowest death rate on record for the United States. Preliminary reports for the first six months of 1934 show a somewhat higher rate in many places. During the year under report, the public health service conducted several studies in places where the economic depression has been most severe, and the results showed higher sickness rates in families most acutely affected by economic conditions. The birth rate again declined, there were 16.4 births per thousand of population in 1933 as compared with 17.4 in 1932. The infant death rate was 58.2 per thousand live births. Three diseases reached the lowest death rates ever recorded: tuberculosis 59 per hundred thousand; typhoid 3.5 and diphtheria 3.9. Although there were no widespread epidemics, three unusual local epidemics of major importance are discussed in the report: amebic dysentery in Chicago,

affecting approximately 690 persons, epidemic encephalitis in St. Louis, which caused 1,100 cases with more than 200 deaths, and poliomyelitis in California, which started in May 1934 and extended beyond the end of the fiscal year. Nearly 400,000 cases of measles occurred in the calendar year 1933, and 656,000 cases were reported to the Public Health Service during the first half of 1934. Less than 7,000 cases of smallpox were reported for 1933, with less than forty deaths. Medical officers of the service by inspection of incoming vessels and airplanes at both foreign and domestic ports prevented the introduction of any quarantinable disease into the United States. Altogether 15,007 vessels and 3,668 airplanes and their passengers were inspected. The International Sanitary Convention for Aerial Navigation was signed on behalf of the United States, April 6, 1934. Vessels operating within the country are also inspected; the report notes that for the first time since inspection was inaugurated there was not a case of typhoid on boats plying the Great Lakes. Among the varied activities of the service during the year was its participation in the emergency civil works program. Three projects were carried out: assistance to fourteen states in malaria control under which more than 6,000 miles of drainage ditches was dug, construction of more than 225,000 sanitary outdoor toilets in twenty-two states and sealing of 7,000 openings in abandoned mines to remove acid wastes from water supplies in Alabama, Pennsylvania and West Virginia. In the research division, in addition to study of epidemics, the program included investigations of cancer, rheumatic heart disease, the use of atabrine in treatment of malaria, pellagra and dietary factors in the production of cataracts. Examination of children of leprosy parents over several years has demonstrated that it is possible to detect changes in the nerves and the capillary system well in advance of clinical manifestations of leprosy. Other investigations were made to determine the mode of entrance of the leprosy bacillus. During the year 212 liters of vaccine for Rocky Mountain spotted fever was manufactured at the laboratory at Hamilton, Mont. for general use and 40 liters more for the Civilian Conservation Corps. A new laboratory building at Hamilton is almost completed. A total of 385,953 cases of syphilis, gonorrhea and chancroid was reported, a slight decrease from the preceding year. The clinic maintained by the service at Hot Springs National Park, Ark., cared for 6,682 patients, a greater number than ever before, owing largely to the great number of homeless transients who poured into the city during the year the report said. The first United States Narcotic Farm, which will be under the control of the division of mental hygiene, will be completed and ready to receive patients in April. Funds have been made available through the public works program for beginning construction of the second farm at San Antonio, Texas. The twenty-five marine hospitals operated by the service together with relief stations in ports not served by these hospitals, cared for 305,155 patients, 42,611 having received treatment in hospitals and the remainder office treatment. In May 1933 a new administration building was opened in Washington, D. C. In closing his report the surgeon general made a number of recommendations for improving the public health. As part of the national defense against disease, the federal health service should cooperate with states on a more substantial basis than in the past, the surgeon general declared. He urged that quarantine regulations in the Panama Canal Zone be made uniform with those in force at other United States ports and that the Convention for Sanitary Control of Aerial Navigation, already signed by this country, be ratified as soon as practicable. Restoration of adequate appropriations for efficient operation of the marine hospitals and for control of venereal diseases was also pointed out as a necessity. Finally, the report asserts that the service is understaffed. Important matters in the regular work as well as the emergency activities of the government have made it necessary to detach experienced officers from their duties leaving the latter to be performed by untrained personnel. The financial statement shows that of an appropriation of \$10,630,587 there was expended a total of \$8,721,451. The entire personnel at the end of the fiscal year included 10,727 persons. Of this number, however, 4,674 are collaborating epidemiologists, mainly officers of state and local health organizations who receive only nominal compensation for furnishing vital statistics or similar services. The statement also includes all part time employees and those on a fee basis.

Too Much Specialization in the Training of Nurses

At an inquiry into the training of nurses in Scotland, evidence was given by the department of health summarizing the history of nurses' training over the last fifty years. The status of nurses has improved greatly in the last twenty to thirty years, but still greater improvement is looked for, which will bring the profession nearer the standard of other professions. At present training is too sectionalized. This applies even to general hospitals, which fifty years ago were in fact "general," as they were the only hospitals. Now as the result of the development of special hospitals, general hospitals deal with a much narrower field of disease. Under existing circumstances a nurse wishing to obtain an all round training, embracing all sections of nursing, must spend a much longer time than in other professions. The question has arisen whether by cooperation between the various hospitals it would be possible for the nurse to pass rapidly from hospital to hospital and obtain an all round training in a reasonable time. If training of this kind could be taken in, say, five years, the nurse would be free thereafter to specialize in any branch to which she felt drawn. Evidence was given by witnesses from the Board of Control (the board which controls lunacy administration) that it would be an advantage if nurses in mental institutions were given general training. If they had this, the period of further training in a mental disease hospital could be substantially reduced.

The British Medical Association and the Registration of Osteopaths

The latest attempt of the osteopaths to obtain registration and the getting of a majority in favor of their bill in the house of lords were reported in a previous letter. The bill has been referred to a select committee. Four bills have been introduced by them since 1931. Alive to the danger of the situation, the British Medical Association appointed a special committee to draw up a memorandum on osteopathy for submission to the council. The memorandum describes the foundation of osteopathy in 1874 by Still of Kansas City, its development, theory, technic and practice, and makes the following criticisms. Osteopathy claims to have discovered a hitherto unrecognized and highly important cause of disease—"the osteopathic lesion"—which is defined as "a structural derangement, no matter how small or where found in the body, which interferes with the normal functioning of human mechanism." Such lesions are usually regarded as spinal and are said to be palpable and curable by manipulation. They are held to be responsible for most of the diseases of the human body. Thus the basis of modern medicine and surgery—physiology and pathology—as evolved by scientific research and taught in the medical schools is considered to be false, and bacteria as causal of disease and biochemical changes are of little significance. But what is the evidence for the osteopathic theory? Osteopathic literature is almost devoid of any pretense at scientific investigation. There is not a vestige of evidence to support the claim that the osteopathic spinal lesion is the principal cause of disease.

But there are indications that many osteopaths are retreating from these disturbing implications and are emphasizing the value of manipulative methods rather than its theoretical basis. A desire to incorporate all the medical curriculum, except drug therapy is also evident. And there are signs that even this exception is being abandoned. The osteopath actually claims to cover the whole field of general medicine, thus admitting that medical science is necessary to him in his practice if not

in his theory, and wishes to be regarded as a healer equipped with a full medical training. There is therefore no reason why he should not follow the same procedure as the medical student and satisfy the General Medical Council as to his knowledge. He can thus qualify and thereafter practice any system he likes. The granting of registration for less than the full medical curriculum would be against the public interest. The position of the medical profession is that a necessary preliminary to osteopathic or any other form of treatment is diagnosis—that the minimum training for competence in diagnosis is the full medical curriculum, that any one who has passed this is free to practice osteopathy. The proposed registration of osteopaths would cause confusion in the public mind by creating registers of different standards. Modern medicine and osteopathy cannot both be right.

To these carefully reasoned criticisms the osteopaths have made no answer, except to allege motives. They say that the British Medical Association, from the narrow standpoint of professional interests, desires to prevent the public from enjoying the benefits of osteopathy. That the association has never asked that osteopaths should be prevented from practicing and has only presented arguments on public grounds against persons with an inferior standard of medical education being allowed to represent themselves as competent for the treatment of all diseases, like properly qualified physicians, is calmly overlooked.

An Industrial Museum Devoted to Safety

There is in London a unique museum, a permanent collection of methods, arrangements and devices for promoting the safety and health of the factory worker. All power driven machinery is a source of danger. In factory accidents last year 523 persons were killed and 104,119 injured. If accidents in building operations and at docks are added, the number of killed is brought up to 688 and of injured to 112,572. The sum paid in compensation is more than \$10,000,000 a year, and when medical and legal expenses and loss due to derangement of work are added the total cost is estimated at between \$40,000,000 and \$45,000,000 a year.

A workman cannot be relied on always to ensure his own safety. A momentary lapse of attention may be disastrous. He may disregard and even deliberately set aside a protective appliance if he thinks that it hinders his work. Hence the greater need of mechanical protection.

In the health section of the museum are divisions devoted to the principal industrial disease, lighting, heat and ventilation, and welfare work. The museum is open to the general public, but it is mainly useful to employers and workers. It is useful also to designers of factories and to physicians. The claim is made that the appliances shown would prevent four out of every five factory accidents.

Poison Gas Warfare

At the Institute of Chemistry, Dr. Hervert Levinstein, one of the poison gas experts during the war, in a lecture said that the widespread notion that science had made war so dangerous that it was less likely to happen was based on a fallacy. The application of chemical science to war had not made war more dangerous either to soldiers or to civilians but it had given fresh possibilities for effecting a strategic surprise that might decide a campaign. It was this and not greater brutality that was the distinguishing feature of chemical warfare. Far more destruction of property, greater mortality and suffering were caused by dropping high explosive or incendiary bombs from aircraft than by using gas-filled shells. But gas might be more effective in causing a panic among untrained and unprotected civilians. The wars that devastated Europe in the seventeenth and eighteenth centuries were proportionately more wasteful of life than the great war, in which casualties were caused chiefly by the lack of invention—by reliance on mere

numbers of men and projectiles. The casualties caused by gas to the American troops, who arrived at the front when the use of gas had reached its maximum, numbered 75,000, of which only 15 per cent were fatal. But of their total casualties (275,000), 30 per cent proved fatal. This was an instance of what had been proved to be generally true—that toxic substances, such as mustard gas and phosgene, caused far less mortality than high explosive shells but were more effective in military results. Thus science had not made war more dangerous to life.

Nutrition Clinics for London School Children

The Labor majority of the London County Council has introduced a number of new arrangements for the medical and dental treatment of school children. These include additional treatment centers, dental inspection and nutriment for children under treatment, the establishment of nutrition clinics and new methods for the early treatment of ear, nose and throat diseases. Five nutrition centers are to be established in London. Cases will be referred to these by school physicians, teachers and the care committees. Each child will be given a thorough examination to ascertain whether its physical condition may be due to dietetic deficiency. If so, advice will be given to the parents and, when possible, nutritives and tonics, such as cod liver oil, malt and iron, will be provided. It is proposed to arrange for the extension of dental inspection and treatment facilities, so that all children in the schools shall be inspected by the dental surgeons once a year and the consequent treatment given.

The Lack of Control of Pharmaceutical Products

The necessity of a stricter supervision of the innumerable pharmaceutical products is being felt both in France and in Belgium. In France the practitioner has his choice of more than 5,000 preparations. The Council on Pharmacy and Chemistry of the American Medical Association was held up as a model which other countries could well afford to adopt in an article by two Belgian professors, Dautrebande and Zunz, in the Dec 1 1934, issue of the *Paris medical*. At present any one without any special training or diploma can manufacture and sell to the public any remedy he pleases. Nothing prevents the sale of these preparations, no matter how little basis there exists for the extravagant claims made to cure every known ailment. Sometimes a specialty for the publicity of which large sums are spent is composed of harmless ingredients without any therapeutic value. In other cases the analysis shows that the preparation does not correspond at all to the advertisement and the patients instead of being benefited grow worse with subsequent unnecessary prolongation of the disease. The physician himself is led astray by the glowing descriptions and the generous number of samples sent by the manufacturer. Uncontrolled publicity has done far more harm than one would imagine hence many European countries have appointed committees to study the question, but generally the recommendations of such bodies have not had much real effect.

The authors of this article quote the organizations of control in Belgium, the Netherlands and Switzerland. In Belgium a sample is subjected to analysis, which has the sole object of verifying that the specialty actually contains the ingredients claimed for it by the manufacturer. In reality, as the authors state the chief object of the analysis is to assure the druggist who is to sell the product. No responsibility is assumed as to the therapeutic value of the specialty, because the control organizations have no funds at their disposal to verify the biologic action of the preparations and also have no authority over the publicity claims of the manufacturer. The control of

the specialties is better organized in the Netherlands, but even there the funds at the disposal of the council on pharmacy are inadequate, only about \$5,000 a year, and hence the analyses are done in the various university laboratories. The Institute, as the control body is termed, issues, at intervals of six months, monographs containing critical analysis of our knowledge of new remedies, which are sent to all physicians and pharmacists. The control of pharmaceutical specialties in Switzerland was not organized until 1932, when a central laboratory for analyses was established at Berne. The chief object is to verify that the preparation contains the ingredients claimed for it by the manufacturer. More attention is paid to the drugs included in the Swiss pharmacopeia than to the analyses or control of nonofficial remedies.

The remainder of the article is devoted to a detailed description of the Council on Pharmacy and Chemistry of the American Medical Association, and a plea is made for the use of this body as a model for all countries that wish to control the rapid increase in pharmaceutical specialties of good bad or indifferent composition. Some such control is certainly needed in the near future in France.

Decline in French Birth Rate

France has been termed a "country of bachelors and one child families." Paul Ballard in a recent article stated that the fall in the birth rate is assuming the proportions of a national peril. During the last sixty years the population of Germany has increased 24 million and that of Great Britain 19 million, while that of France increased only 2 million. Italy, Great Britain and Japan combined are as large in area as France, yet these three nations combined have a larger number of children than France. In 1830 there was an average of four births to a family. In 1890 it had decreased to three, and today it is two. During the first nine months of 1933 there were 30,000 less births than in the corresponding period of 1932.

Attention has been called to the decline in birth rate of the white race all over the world.

History teaches that whenever a country has attained a high degree of civilization, the birth rate begins to decline and then follows invasion or colonization by more fertile races on its soil. The present condition of France is not unlike that of Rome, which was obliged in its later period to depend on paid foreigners to defend it to see wheat from other countries supplant its own agriculture to find that the rural population flocked to the cities and the citizen neglected his responsibility and avoided paternity. Soon after these events, Rome was invaded by barbarians and its ruin soon followed. Even in the country districts of France there is a tendency to have smaller families to avoid added expense and division of property, acquired through years of thrift such as only the French peasant knows.

Only by direct aid in the way of reduced taxes, rewards for large families, heavy taxation of bachelors, reduction in the number of women engaged in commercial pursuits, and severe laws against abortion, will the birth rate rise. Such encouragement has been given in the form of legislation and other measures in Italy and Germany during recent years. In Italy, more births were reported during the first six months of 1934 than in the previous two years.

Scarcity of Physicians in Rural Districts

The department of public health has issued a circular again calling attention to the excessive number of physicians, dentists and pharmacists in cities and the small number who are willing to settle in rural communities. An office has been opened in the department of public health to gather facts and give information regarding the inducements offered by small communities for the physician, dentist and pharmacist. These inducements

consist in salaries or guaranties and all heads of the eighty-six departments into which France is divided have been notified to cooperate in furnishing medical care to country districts. In the *Concours medical* Dec. 9, 1934, Noir states that the great difficulty in finding recent graduates who would be willing to practice in these rural communities is that the latter are so small that one could not earn a living. Quite often the inducements offered prove to be illusory, owing to the fact that some enthusiastic official overestimates the possibilities of developing a paying practice, or for political purposes some official wishes to set up an opposition to a practitioner in an adjacent community. This writer warns young physicians and dentists to consider well the verbal promises of a fixed revenue, by the local officials, and to insist on a written contract.

It is suggested that before announcing an opening, the Bureau of Information should be certain that the offer is genuine, and if a district is too poor to be able to assure a sufficient income it would be wise for the central government in the cities or county seats under whose jurisdiction the district is placed to grant a subsidy. This already exists in the mountainous country of southeastern France. The great danger of course, lies in the fact that the medical man becomes one of the already large army of public officials.

French Tuberculosis Congress of 1935

The 1935 session of the French National Tuberculosis Congress will take place in April at Marseilles. The subjects to be discussed are the role of the tuberculous ultravirus in human and experimental pathology, the indications and results of thoracoplasty in the treatment of tuberculosis, the fight against tuberculosis in North Africa and the prophylaxis of tuberculosis in the navy.

BERLIN

(From Our Regular Correspondent)

Nov. 26, 1934

Castration and Problems of Heredity

Dr. Schlegel, director of the state hospital attached to the examination prison at Moabit, Berlin, recently published the first report on castrations performed. The largest number of castrations in compliance with the latest law in Germany are performed in this institution. The application of the law of Nov. 24, 1933 to habitual criminals is according to Dr. Schlegel, in many cases entirely vague. Besides punishment by imprisonment, the court may also interpret castration not as a punishment but as a "regulatory means of protection and improvement" for habitual criminals and as a protective measure for the people who may fall victims to sexual criminals. In this state hospital there have been 111 castrations performed since the law became effective. Twenty more prisoners in being prepared for castration were subjected to the strictest examinations. A photographic picture definitely retains the identity of every one. The blood, the blood pressure and the sedimentation rate were analyzed. The voice and its tonal color were fixed on phonographic records. A thorough opinion was formed about the mind and intelligence of every one. The operation for amputation of both testicles was performed under local anesthesia within about eight minutes. Thus far no deaths have occurred. The patients were between the ages of 20 and 60. A central national card index of patients presenting hereditary diseases will be established, as stated by a communication of the medical department of the national health bureau, and in this way a systematic survey of the hereditarily diseased patients will be produced. This will serve as a basis of evaluation for the new racial and eugenic law. It must begin with the indexing of patients having mental diseases in order to make use of the large material accumulated in the archives of institutions for mental patients. The national health bureau has prepared

an index form containing eighty questions pertaining to personal data, precise psychiatric diagnostic data and hereditary disease data. Preliminary work for carrying out the law has been done at the hygienic institute of the University of Münster (Westphalia). Dr. Mehring has tested the fecundity of the parents of mentally deficient individuals and of pupils not able to meet the requirements of a grade school. The results showed that in Münster the fecundity of the hereditarily inferior families is one and a half times greater than the fecundity of hereditarily healthy families.

The question is raised as to whether biology and the science of heredity, especially, are in a position to establish a support for the legislator. Some lectures given in Bremen under the title "Prevention of Useless Lives" are of interest. From the first of the lectures given by the late Professor Baur, director of the Kaiser Wilhelm Institute for Research on Breeding, it would appear that the originator of the law did not go far enough. He refers to natural selection. The theory in bare outline is that man as a species may stay healthy only if the natural selection, which is eliminated in a cultural status, is reestablished by conscious efforts directed toward the prevention of hereditarily inferior types. There is, however, no natural selection but only natural elimination, and the sociologist W. E. Muhlmann of Berlin has so stated in the second lecture, entitled "The Selection Process in Human Society." In the third lecture, Dr. F. K. Walter, professor of psychiatry and director of the Institute for Mentally Diseased Patients at Bremen, objected to the manner in which the legislator applied the mendelian law of heredity to the human race, whereby he entirely overlooked the difficulties of its application. Walter emphasizes that the mendelian law is fulfilled, primarily, in case of large numbers, so that a dominant character, for example, a good or a bad quality of the parents, will reappear in 50 per cent of the children. One must therefore figure on 1,000 children in order to expect the dominant character in 500 children. The smaller the number, the more uncertain the expected percentage becomes. In Germany the average number of progeny being three, the prediction becomes naturally less safe than in animal and plant research, in which the number of progeny is high. Secondly, the human progenitors possess, by reason of cross breeding, not merely hundreds but thousands of individual hereditary factors, and this point introduces a new factor of unsafety into the prediction. Walter gave some striking examples. He discussed a family with acute hereditary mental disease, which was under his observation for a long time. Members of the family had a remarkable proclivity for mathematics, and at least three mathematicians of world fame and a line of scientifically recognized naturalists were born into the family. For these reasons Walter is against unconditional sterilization in cases of the following hereditary diseases, included in the German sterilization law: congenital, hereditary deaf-mutism, certain forms of hereditary weakness of mind, certain forms of epilepsy and schizophrenia. He cautions, furthermore, against an overestimation of sterilization prospects, even in cases in which sterilization is in order, because the inheritance mechanism in the majority of hereditary diseases is unknown. The view of negative eugenics was stressed in the fourth lecture by E. H. Rosenberg-Münster, jurist. If, for instance, all epileptic patients of a generation could be sterilized, this disease would not disappear, the old sources would break out again (recessive hereditary process), and new sources would develop (mutations). The retrogression would be slight.

The First Professorship for Public Health

The first professorship in public health has been established in the University of Munich. Professor Dr. Schultze, the new state commissioner for public health in Bavaria, has been appointed lecturer. In his inaugural lecture he pointed out first

the negative side of his professorship, namely, combating the errors in medicine due to specialization. The problems of the new discipline in science are, as he stated, racial supervision, dwelling and colonization problems, social insurance, and determination of the useful in folk remedies, the single great objective being that public health is political power.

ROME

(From Our Regular Correspondent)

Dec 15, 1934

Congress of Internal Medicine

The Società Italiana di Medicina Interna held recently its fortieth national congress, in Rome. The first official topic concerned vaccines and nonspecific treatment in infectious diseases. Dr. Introzzi spoke on the therapeutic value of vaccines in undulant fever. Specific vaccine given by vein is the most efficacious treatment of brucella infection in man, as has been proved by the results of its use since 1926 by many physicians. The best effects are obtained when the vaccine causes a general, intense reaction. Vaccination should be regarded as a desensitization of the organism in a condition of allergy rather than as a stimulation of the natural powers of defense of the organism. Then the useful reactions would be due to a given dose of the vaccine, which would be determined in each case by the administration of injections of tentative doses. Intravenous injections are not dangerous and have no limitations related to the stage and clinical form of the disease, if given with the proper technic. In the clinic at Pavia the vaccines are prepared by Pfeiffer and Kolle's method. The emulsions are prepared in phenolated physiologic solution with the cultures of bacteria killed by heat in a water bath.

The second official topic was on pleural diseases in the army. Dr. R. D'Alessandro of the Scuola di Sanità Militare said that the statistics from 1921 to 1930 prove that pleurisy is one of the most frequent and grave diseases among soldiers in active service and that it is related to the climate and the weather of the territories occupied by the soldiers as well as to the military service to which the soldiers belong. The highest rate of mortality is observed during May, June and July, that is, shortly after the recruits enter service. In tuberculous pleurisy, which is the most frequent form, the inflammation of the pleura may follow the formation of an early tuberculous infiltration, it may be caused as an allergic reaction to the reactivation of tuberculous foci (in the secondary stage of tuberculosis) or it may appear at the final period of tuberculosis. In cases of traumatic pleurisy, one should estimate the preexisting bacterial and the recent traumatic factors and also determine the nature of the trauma and when it occurred. Age is important among recruits. Most of them are about 21, an age at which the reactivation of latent tuberculosis is frequent. He observed in a group of 600 tuberculous patients attending the Centro di accertamento diagnostico dell'Ospedale Militare of Florence 300 who had had a preexisting pleurisy. The incidence of tuberculosis was higher in patients of this subgroup than in those who had not previously suffered from pleurisy, and form of tuberculosis was more serious in patients of the first than in those in the second subgroup—that is, 35 per hundred to 22 per hundred. It is advisable to make periodic examinations for the early diagnosis of tuberculosis among soldiers who enter the army after having had pleurisy.

The last official topic was meteoropathies. Dr. Nicola Pende, a senator and physician in Genoa, discussed the pathogenesis and treatment of meteoropathies, which he defined generally as local autonomic and protopathic morbid reactions causally and chronologically related to sudden meteorological changes. The speaker classified the condition, from a clinical point of view, into three groups: (1) syndromes caused by special winds (2)

reactions caused by the passage of cyclones and (3) accidents appearing coexistently with the passage of large solar spots. The speaker pointed out two important facts. The weather, not by itself but in association with all factors of the meteorological environment are the meteoropathic agents, and the patients are in a condition of neuro-endocrine unbalance with excitability of the sympathetic nervous system.

Dr. Bufano of Genoa spoke on the experimental physiopathology of meteoropathic reactions. The speaker called attention to the importance of the atmospheric conditions of electricity, temperature and humidity in the etiopathogenesis of meteoropathies morbid conditions improperly nominated "cyclo-nosis." Meteoropathies are essentially neurosis of the sympathetic nervous system, the central and peripheral reactions of which take place under the action of the atmospheric elements through the skin and the mucous and alveolar surfaces of the respiratory tract.

The Congress of the Italian Surgical Society

The forty-first congress of the Società Italiana di Chirurgia was recently held in the headquarters of the surgical clinic of the University of Rome under the chairmanship of Dr. Roberto Alessandri. The first official topic was surgery of the colon, presented by Dr. Dominici of the University of Perugia. The speaker discussed the clinical importance of congenital and acquired malformations of the colon, with special reference to megacolon. True megacolon, the speaker believes, originates in an unbalance of the sympathetic-parasympathetic functions, the cause of which is unknown. The theory of a sympathetic hypertonia as the cause seems to be confirmed by the satisfactory results of lumbar sympathectomy in the treatment of the condition. An abnormally long colon does not imply surgical intervention unless it causes obstruction or painful crises. Chronic intestinal stasis presents many unsolved problems. The tendency is to consider it as a syndrome that may appear in several diseases rather than as a disease by itself. In discussing trauma of the colon he said that wounds only of the colon have a benign evolution while a high mortality rate follows the wounds of the colon that coexist with wounds in some other viscera. In cases of associated colonic and visceral wounds, immediate surgical intervention is indicated. One may say, schematically, that surgical intervention is indicated only as an exception in acute peritonitis without complications, while its indications are more frequent in chronic peritonitis. A simple laparotomy is indicated in ulcerous tuberculous colitis, and there are other operations indicated in the different forms of tuberculosis of the colon.

Alessandri spoke also on diverticula of the colon, obstruction, volvulus, intussusception and polyposis. Several other articles on the same topic were read and a general discussion followed.

The second official topic, bronchiectasis, was presented in connection with the Società di Medicina Interna. Dr. Omodei Zorini of Rome covered the medical aspect of the topic. Bronchiectasis may be congenital or acquired. The acquired form originates in infections of the respiratory tract. At the onset only the mucosa is involved then the structure of the bronchial walls, then a mechanism of pulsation and traction, due to the stagnation of the secretions, is established, and lastly pleural and peribronchial sclerosis develops. In bronchiectasis with poor bronchial drainage, it is advisable to resort to bronchoscopy with aspiration of secretions, pneumothorax or intratracheal instillations of antiseptic drugs.

Dr. Vallebona of Genoa spoke on the importance of bronchography in bronchiectasis either by itself or with the refinement of stratigraphy, a method by which superposition of shadows is avoided and only a given stratum of the object is reproduced. The roentgen picture of large congenital pulmonary cysts may closely resemble that of pneumothorax. The roentgen examina-

tion is of paramount importance, because with it one can determine whether or not the given condition is in an evolutionary or a stationary stage.

Dr. Alessandri was the official speaker on the subject of surgery in bronchiectasis. The preoperative preparation of the patient, especially by means of postural drainage is important. Phrenico-exeresis, thoracoplasty and plugging are the methods indicated to induce collapsotherapy, the results of which may be good although not permanent. In suppurative complications, pneumotomy and frequently partial pneumectomy is the necessary operation. The speaker is still undecided whether lobectomy should be performed in one operation or in two or more. His statistics show four deaths in forty-five operations by the first method and six deaths in fifty-seven operations by the second. His own experience includes seventy-two cases of bronchiectasis with twenty-seven operations.

Dr. Lasagna of Parma spoke on bronchoscopic diagnosis in bronchiectasis. In peroral endoscopy, to prevent incidents during the introduction of the instrument, it is necessary to have a thorough knowledge of the anatomic details and of the frequent abnormal disposition of the main and secondary bronchial branches. It is necessary to have in mind the functions of the ciliated epithelium, the mucus, the musculature and the current of air during either inspiration or expiration. The speaker described the various types of bronchoscopes now in use. Block anesthesia of the laryngeal nerve suffices in most cases, in a few cases, general anesthesia is necessary. There are some contradictions related to the anesthesia, to the pulmonary diseases present, and to general diseases. In the general discussion that followed, Dr. Micheli of Turin said that bronchiectasis is most frequently of congenital origin and that, generally speaking, the medical treatment gives satisfactory results.

BUDAPEST

(From Our Regular Correspondent)

Dec. 14, 1934

Method of Preparing Cancer Statistics Should Be Revised

According to Dr. K. Wolff the method of preparing cancer statistics should be revised. The only reliable statistics are those founded on diagnoses established *in vivo* by postmortem protocols, on histologic sections and on the data afforded by compulsory death certificates. Unsupported clinical diagnoses of cancer, according to calculations, are erroneous in from 15 to 30 per cent of cases, and exact statistics cannot be expected without histologic controls. The verdicts of coroners, some of whom are not medically qualified, are unreliable. Thus, statistics that appear to prove the increase of cancer mortality may indicate only the development of the science of diagnosis, whereas cancer mortality rises in such statistics, the number of cases labeled senile marasmus, cause unknown, and other indefinite diagnoses decreases. Well trained physicians know that nobody dies solely from senile debility, if the patient had no other disease he would be certain to have had myocardial degeneration or a bronchopneumonia. Postmortem statistics are also unreliable, because they do not reflect the conditions of the whole population but of the hospital class. This objection holds true still more with regard to statistics based on histologic material alone. The fewer the cases utilized in the compilation of cancer statistics, the less reliable are the results. In one hospital the leading surgeon may have a predilection for cancer cases hence the cancer turnover is high. Another hospital hardly admits cancer patients because its surgeons work on other lines the number of cancer cases here will be low. Such sources of error can be eliminated by the collation of the material of many hospitals when those which have large children's departments will serve to balance others deal-

ing exclusively with cancer cases. Thus a fairly accurate picture of the conditions of population could be obtained, but only of the hospital class.

The statistics heretofore published do not prove in Dr. Wolff's opinion, the assumption that the rate of mortality from cancer shows a rising tendency. A relative rise is the obvious corollary of the fact that the number of deaths from other curable and preventable diseases is diminished. But this means no more than that the human race at present is unable to defend itself against cancer because neither the cause the therapy nor the prophylaxis of cancer is known. The average duration of life is increasing all over the world. Cancer is the disease of elderly persons. If the average duration of man's life is increasing, there are more elderly persons, that is to say, more people reach the age at which cancer is apt to occur. In Dr. Wolff's view the apparent increase in the incidence of cancer has been too much emphasized. The mortality rate of every disease displays some oscillations if a comparative scrutiny is made of the statistical material available over several years.

The statistics collected at Budapest show no progressive increase of cancer, its occurrence being fairly constant. Between 1919 and 1923 among the necropsies in the Budapest University clinics on patients over 20 years of age the cancer rate amounted to 12.42 per cent, while between 1924 and 1928 it amounted to 12.52 per cent. Since in quite recent years a larger proportion of different sections of the population seek relief in hospitals and are subjected to routine *postmortem* examinations, it can be believed that the data provided by *postmortem* statistics today are nearer to reality, and more nearly representative of the truth, than the other statistics.

The Teeth of School Children

The school medical inspectors of the municipal schools, in their recent report speak strongly as to the amount of dental cases, and as to the absolute indifference shown by the parents when their attention is drawn to it. Most of them think it is hereditary—they themselves had bad teeth, and their children also must suffer. Of 1,500 girls examined only 432 had satisfactory teeth, and the same proportion was found also in boys. The lack of interest taken as to cleanliness and preservation of teeth is the more regrettable when it is stated that half of the children leaving school and suffering from dental caries were yet in such a condition that their teeth could be saved at but little expense. Conservative dentistry, however, is unknown among the children.

Marriages

FRANCIS WILLIAM HOBART, Lake City, Iowa, to Miss Blanche States of Coon Rapids, in Rockwell City, Dec. 6, 1934.

WILLIAM ORRIN McDOWELL, Grundy Center, Iowa to Miss Faye Hanway of Des Moines, Nov. 23, 1934.

IRVING MAXWELL CASEBEER, Clinton, Ind., to Miss Mary Eaton Short at Rockville, Oct. 20, 1934.

ROBERT C. CRUMPTON Webster City, Iowa, to Miss Esther Isvik of Jewell, Nov. 29, 1934.

JOHN HEINZ VENABLE to Miss Louise Felker Ware both of Atlanta, Ga., Dec. 18, 1934.

ESTHER MARGARET KIRK to Mr. Roy A. Foster, both of Oklahoma City, January 7.

HARLEY BENN LEHNERT to Miss Gladys Knierim, both of Toledo, Ohio, Dec. 1, 1934.

HENRY LEWIS COOPER, Denver, to Miss Helen Lucile Ratner of Chicago, Nov. 18, 1934.

CHARLES A. TERHUNE, Rupert, Idaho to Miss Ruth Story of Burley, Nov. 30, 1934.

THEODORE L. BORDSEN to Miss Vi L. Cleverley, both of Seattle, Dec. 8, 1934.

NORRIS E. HAROLD to Miss Cora Schoen both of Indianapolis, Dec. 23, 1934.

Deaths

Walter Lincoln Burrage * Brookline, Mass., Harvard University Medical School, Boston, 1888, since 1909 secretary of the Massachusetts Medical Society, clinical instructor in gynecology at his alma mater, 1893-1895 house physician to the Boston City Hospital, 1886-1888, and the Woman's Hospital, New York, 1888-1890 visiting gynecologist to the Carney and St. Elizabeth's hospitals, Boston, 1890-1903 surgeon to outpatients, Free Hospital for Women 1890-1901, secretary of the Boston Medical Library, 1911-1926 in 1912 collaborated with Dr. Howard A. Kelly on two volumes of *American Medical Biography*, rewrote Dr. Kelly's book on "Appendicitis" in 1910 assisted him with a book called *Medical Gynecology*, in 1920 *American Medical Biographies* and in 1928 *Dictionary of American Medical Biography* author in 1910 of "Gynecological Diagnosis" in 1923 *A History of the Massachusetts Medical Society, 1781-1922* and in 1931 *Catalogue of Honorary, Past and Present Fellows Massachusetts Medical Society, 1781-1931*, in 1930 contributed in the fifth volume of the *Commonwealth History of Massachusetts* a chapter on "Medicine in Massachusetts" aged 74 died, January 26

E. Otis Smith * Cincinnati Medical College of Ohio, Cincinnati, 1896 Member of the House of Delegates, 1910-1911 1913, 1918 and 1921 American Medical Association and secretary of the Section on Genito Urinary Diseases 1918-1919, and Secretary of the Section on Urology 1919-1920 past president of the Ohio State Medical Association member of the American Urological Association, fellow of the American College of Surgeons professor of urology University of Cincinnati College of Medicine 1908-1933 director of the urological service Cincinnati General Hospital aged 63 died Dec. 26, 1934, in the Good Samaritan Hospital, of pulmonary edema

Robert Uriel Drinkard * Wheeling, W. Va. Johns Hopkins University School of Medicine Baltimore, 1908, Member of the House of Delegates of the American Medical Association in 1931 councilor of the first district of the West Virginia State Medical Association past president of the Ohio County Medical Society, fellow of the American College of Surgeons served during the World War on the staffs of the Ohio Valley General Hospital and the Wheeling Hospital, aged 55 died suddenly, January 3, in Bunnell Fla. of myocarditis

Frank Harrison McGregor * Mangum Okla. University of Louisville (Ky.) School of Medicine 1913 formerly secretary of the Greer County Medical Society councilor of the second district of the Oklahoma State Medical Association at one time member of the state board of medical examiners served during the World War part owner of the Border-McGregor Hospital and Clinic aged 47 died January 5, near Bowie Texas, when he was struck by a truck

Charles Benjamin Younger * Chicago Northwestern University Medical School, Chicago 1902 assistant professor of otolaryngology at his alma mater, fellow of the American College of Surgeons, past president of the Chicago Laryngological Society aged 59 on the staff of the Wesley Memorial Hospital where he died January 11 of coronary thrombosis

Edwin William Stork * Somerville, Texas, University of Texas School of Medicine Galveston 1920 served during the World War for many years member and president of the board of education and health officer of Somerville on the staff of the Sarah B. Milroy Hospital Brenham, aged 42 died Nov. 19 1934 as the result of septicemia

William Ainslie Goodall, New York Victoria University Medical Department Coburg Ont. Canada 1884 member of the Medical Society of the State of New York for many years on the staff of the Morrisania City Hospital aged 72 died January 6 in the Wickersham Hospital of influenza and gastric hemorrhage

Marshall Blair Morgan, Huntingdon Pa., Jefferson Medical College of Philadelphia 1915 member of the Medical Society of the State of Pennsylvania past president of the Huntingdon County Medical Society on the staff of the J. C. Blair Memorial Hospital aged 41 died Nov. 24 1934 of infectious hepatitis

Kenneth Simms Caldwell * A Surg. Lieut. U. S. Navy, retired St. Paul University of Minnesota Medical School Minneapolis 1918 entered the navy in 1919 and was retired in 1921 for incapacity resulting from an incident of service aged 42 died Oct. 2 1934 of a gunshot wound in the left side of the chest

John Fox Connors * New York, University of the City of New York Medical Department, 1895, served during the World War, member of the American Surgical Association, fellow of the American College of Surgeons for many years on the staff of the Harlem Hospital, aged 61 died, January 5, of embolism

Lee Hugo Koehler, Alliance, Ohio Harvard University Medical School, Boston 1932 third assistant resident medical officer to the Sanatorium Division of the Boston City Hospital aged 28, died Dec. 26 1934 in a garage at Berlin Center of carbon monoxide poisoning, while making repairs on his automobile

Charles E. Fairman, Lyndonville, N. Y. St. Louis Medical College 1877 member of the Medical Society of the State of New York for many years health officer of Yates, Orleans County, on the staff of the Medina (N. Y.) Memorial Hospital aged 77 died, Dec. 27 1934 of angina pectoris and arteriosclerosis

Ray McKelvey Alexander, Bolivar, Pa., Western Pennsylvania Medical College, 1905 member of the Medical Society of the State of Pennsylvania, served during the World War, for many years member of the school board aged 55, died Dec. 25, 1934, in St. Francis Hospital Pittsburgh, of heart disease

Joseph Adam Weitz * Montpelier, Ohio, University of Michigan Medical School Ann Arbor, 1886, past president and secretary of the Williams County Medical Society, formerly county health officer and member of the school board, aged 85, died January 11 of coronary thrombosis

John C. Knight, Jonesboro Ind. Kentucky School of Medicine Louisville, 1881 member of the Indiana State Medical Association for many years member of the school board formerly member of the state legislature aged 78, died, Dec. 27, 1934 of acute nephritis and myocarditis

Sheldon Eli Cook, Lincoln, Neb. McGill University Faculty of Medicine Montreal, Que., Canada 1884, member of the Nebraska State Medical Association past president of the Lancaster County Medical Society, aged 77, died, Dec. 31, 1934 of carcinoma of the pancreas

Lawrence Wells Whitmer, Chicago College of Physicians and Surgeons of Chicago, 1892 aged 75 formerly on the staff of the Illinois Masonic Hospital where he died January 2, of chronic myocarditis and hypostatic pneumonia following an operation for gallstones

William E. Buxton, West Salem Ill. Central College of Physicians and Surgeons Indianapolis, 1881 member of the Illinois State Medical Society president and formerly secretary of the Edwards County Medical Society aged 76, died, January 2, of pneumonia

Melvin A. Wardwell * Penobscot Maine Bellevue Hospital Medical College New York, 1898 past president of the Hancock County Medical Society on the staff of the Community Hospital, Castine aged 61 died, Dec. 29, 1934, of angina pectoris

Thornton Easley Moore * Trenton Mo., University of Missouri School of Medicine Columbia 1903 past president of the Grundy County Medical Society on the staff of the Wright Hospital, aged 56 died recently of angina pectoris

Warren Laws Snider, Hot Springs National Park, Ark. Medico Chirurgical College of Philadelphia 1902 member of the Arkansas Medical Society served during the World War, aged 56, died suddenly in December 1934 of heart disease

Arthur William Loeber, Milwaukee, Marquette University School of Medicine Milwaukee, 1931 aged 30 was found dead Dec. 29, 1934, of asphyxiation when a gas stove flame was extinguished by a kettle of water boiling over

Byron Monroe Sell * Altoona, Pa. Jefferson Medical College of Philadelphia, 1924 also a minister connected with the Altoona Clinic aged 37 on the staff of the Mercy Hospital where he died, Dec. 9 1934 of heart disease

Augustus E. Venn, Chicago University of Pennsylvania School of Medicine Philadelphia, 1893, aged 69 died, January 7 in the Alexian Brothers' Hospital of chronic myocarditis following operation for intestinal obstruction

Cyrus John Strong, Miami Fla. College of Physicians and Surgeons Medical Department of Columbia College, New York 1891 member of the Florida Medical Association, aged 72 died Dec. 19 1934, of intestinal obstruction

Edgar Carroll, Dayton N. J. Jefferson Medical College of Philadelphia 1880 member of the Medical Society of New Jersey formerly on the staff of St. Peter's General Hospital, New Brunswick, aged 81 died Nov. 18 1934

Frank E. Smith, Portland, Ore., Willamette University Medical Department, Salem, 1898, past president of the Board of Medical Examiners of the State of Oregon, aged 61, was killed, Dec. 30, 1934, in an automobile accident.

Jonas Rhodes Longley ♂ Fond du Lac, Wis., Rush Medical College, Chicago, 1906, served during the World War on the staff of St. Agnes Hospital, aged 55, died, January 2, in New Orleans, of acute gastritis and nephritis.

Lina D. Schwatt, Philadelphia Woman's Medical College of Pennsylvania, Philadelphia, 1912 for many years resident physician to the Philadelphia Hospital for Mental Diseases, aged 68, died, Dec. 22, 1934, of pneumonia.

Hugh Boggs Hawthorne ♂ West Mineral Kan., Kansas Medical College, Medical Department of Washburn College, Topeka, 1913 served during the World War aged 46, was found dead Dec. 24, 1934, of heart disease.

Archibald Nail Dawson ♂ Lakewood Ohio Western Reserve University Medical Department, 1908 on the staff of the Lakewood City Hospital, aged 52, died, Dec. 20, 1934, of glioma of the left cerebral hemisphere.

Arthur Fichell Sampson, San Francisco University of Virginia Department of Medicine Charlottesville 1878 member of the California Medical Association aged 79, died, Nov. 27, 1934, of cerebral hemorrhage.

Clifford Charles Legler ♂ Portsmouth Ohio University of Louisville (Ky.) School of Medicine 1908 on the staff of the Portsmouth General Hospital aged 50, died, Nov. 25, 1934 of perforated gastric ulcer.

William Montgomery Burnett, Greenville S. C., University of Louisville (Ky.) School of Medicine 1905 member of the South Carolina Medical Association aged 58 died January 7, of heart disease.

Robert Gallaher Reynolds Jr., Palo Alto Calif. University of California Medical Department San Francisco 1903 aged 63 died Dec. 10, 1934 in the Stanford Hospital, San Francisco of heart disease.

William Rankin Goley, Graham N. C. College of Physicians and Surgeons Baltimore 1885 member of the Medical Society of the State of North Carolina, aged 81, died, Nov. 26, 1934, of lobar pneumonia.

Harry Edward Bacon, San Francisco Denver and Gross College of Medicine Denver 1908 aged 53, died Dec. 16, 1934, in the Mount Zion Hospital of cirrhosis of the liver and chronic cholecystitis.

Thomas Stephen Augustine O'Connor ♂ Troy, N. Y., Albany (N. Y.) Medical College 1903 on the staffs of St. Joseph's Maternity, Troy and Samaritan hospitals aged 55 died, Nov. 18, 1934.

Paul W. Woods, Atlanta Ga. Meharry Medical College, Nashville, Tenn. 1900 aged 52 died Dec. 27, 1934 in the Grady Hospital, of burns received when the oil stove in his office exploded.

Charles Edward Britto, Stockton Springs Me. Hahnemann Medical College and Hospital of Philadelphia 1899 aged 65, died, Oct. 24, 1934 of coronary occlusion and chronic endocarditis.

Walter C. Hamilton, Kearney Mo. College of Physicians and Surgeons of Kansas City, 1879, member of the Missouri State Medical Association aged 80, died Dec. 25, 1934, of pneumonia.

William Alfred Strauss, Baltimore Johns Hopkins University School of Medicine, Baltimore, 1924 aged 38 died Nov. 22, 1934, in the Laurel (Md.) Sanitarium, of lobar pneumonia.

Alice Hatheway Purvis Robie, Watertown, Mass., Woman's Medical College of Pennsylvania, Philadelphia, 1898, aged 62 died, Oct. 20, 1934 in Alameda, Calif. of arteriosclerosis.

Joseph Anthony Herb, New York College of Physicians and Surgeons, Medical Department of Columbia College, New York 1885 aged 75 died Dec. 27, 1934, of carcinoma of the stomach.

Samuel H. Murphy, Yates Center, Kan., Eclectic Medical Institute, Cincinnati 1896 member of the Kansas Medical Society aged 72, died, Dec. 26, 1934, of carcinoma of the stomach.

Ward Beecher Saltsman, Buffalo, Albany Medical College 1891 member of the Medical Society of the State of New York aged 66 died, January 10 of chronic myocarditis.

Sophie Solotareff Solf, Gary, Ind. Universität Zurich Medizinischen Fakultät Zurich 1911 aged 50 died Dec. 13, 1934 in the Michael Reese Hospital Chicago of heart disease.

John Bruffe Kenagy, Rupert, Idaho, Colorado School of Medicine, Boulder, 1906 member of the Idaho State Medical Association, aged 71, died, Nov. 17, 1934, of heart disease.

William Henry Heidorn, Bridgeton, Mo. St. Louis College of Physicians and Surgeons, 1886, aged 74, died, Dec. 26, 1934, in the Barnes Hospital, St. Louis, of pneumonia.

George S. Hays, Greeneville, Tenn., University of Tennessee Medical Department, Nashville, 1892 aged 72, died, Dec. 25, 1934, in a local hospital, of cerebral hemorrhage.

Albrecht Otto Eckardt, Rodeo, Calif., Medizinische Fakultät der Universität Leipzig, Saxony, Germany, 1889, aged 69, died, Dec. 10, 1934, of a tumor of the kidney.

Ida Elizabeth McCormick, Cincinnati, Pulte Medical College Cincinnati, 1900, aged 68, died, Dec. 30, 1934 in the Bethesda Hospital, of a hip fracture received in a fall.

Henry Paul George ♂ Claremont N. H. Baltimore Medical College, 1912 formerly on the staff of the Claremont General Hospital, aged 50, died, January 1, of carcinoma.

Lovell Hampton Harrell, Plant City, Fla., Tulane University of Louisiana Medical Department, New Orleans 1910, aged 57, died, Dec. 26, 1934, of chronic nephritis.

Samuel B. McGuire, Dover, Ohio, Baltimore Medical College 1893, formerly on the staff of the Union Hospital, aged 67, died, Dec. 6, 1934, of pernicious anemia.

David Watt Sheldon, Carmel Maine, University of Vermont College of Medicine, Burlington, 1898, aged 62, died Oct. 19, 1934, of thrombosis and arteriosclerosis.

William R. Spooner, Fostoria, Ohio, Baltimore University School of Medicine 1899 Toledo Medical College, 1903, aged 65 died Dec. 3, 1934 of bronchopneumonia.

Frederick Wrede, Chicago, Miami Medical College, Cincinnati 1880 also a druggist, aged 84, died, Dec. 30, 1934 of chronic myocarditis and arteriosclerosis.

John W. Merritt, Center Point, Texas, Tulane University of Louisiana Medical Department, New Orleans 1899, aged 75 died Dec. 21, 1934 of arteriosclerosis.

Joseph Price Watson, Hazlehurst Miss., Vanderbilt University School of Medicine Nashville, Tenn., 1903, aged 54, died Dec. 29, 1934 of heart disease.

John Roger Haynes, Albuquerque, N. M., University Medical College of Kansas City, Mo., 1893 aged 62, died, Dec. 27, 1934, of diabetic gangrene.

Martin Luther Gettinger, Palestine, Ill., American Medical College St. Louis, 1880, aged 76, died, Dec. 20, 1934 in Santa Fe N. M., of pneumonia.

Harris Weinstein ♂ New York, University of the City of New York Medical Department, 1891, aged 65, died, January 8, of cerebral hemorrhage.

Thomas E. Brents, Ada, Okla., Reform Medical College, Macon, Ga., 1873, Civil War veteran, aged 88, died, Dec. 29, 1934, of bronchopneumonia.

Addison James Beebe, Sutherland, Neb., Drake University Medical Department Des Moines, 1889, aged 86, died, Oct. 30, 1934 of senility.

Clinton Perley Hubbard, South Paris, Maine, Medical School of Maine, Portland, 1884, aged 85, died, Nov. 19, 1934, of arteriosclerosis.

George S. Roberts, Thompsonville, Ill., Northwestern University Medical School, Chicago, 1892, aged 66, died, Dec. 17, 1934, of pneumonia.

John McCulloch Gourley, Sheet Harbor N. S. Canada, Halifax Medical College, Halifax, N. S., Canada, 1884, aged 75, died, Dec. 11, 1934.

John H. Wylie, Winnsboro, Texas (licensed in Texas, under the Act of 1907), aged 64, died, Nov. 24, 1934, of bronchopneumonia.

Thomas Gilmore Waller, Lowell, Mass., Dartmouth Medical School, Boston, 1886, aged 76, died, Dec. 9, 1934 of arteriosclerosis.

Leon Ackerman, New York New York University Medical College, 1896 aged 65, died, Dec. 22, 1934 of coronary thrombosis.

William James Hagan, Athens Ala., Jefferson Medical College of Philadelphia 1884, aged 72, died, January 1 of pneumonia.

William Lewis Worthington, Camden Ark. (licensed in Arkansas in 1903), aged 72, died, Dec. 23, 1934, of heart disease.

James T. Mills, Gilmore, Ohio Columbus Medical College 1881, aged 81, died January 2, of heart disease.

TREATMENT OF GONORRHEA IN WOMEN

To the Editor —Dr Emily Dunning Barringer in a paper "The Treatment of Gonorrhea in the Female" (THE JOURNAL, Dec. 15, 1934, p 1825) makes the following statement

The greater degree of heat, 130 F as given by the Elliott machine seems unwise during the acute stage because of the softening and relaxation of the cervix, thereby opening up one of the natural barriers to the spread of infection

It is common knowledge that when the gonococci reach the mucous membrane of the cervix or urethra an inflammation is set up. The micro-organisms and their decomposition products stimulate serum exudation, diapedesis, leukocytic infiltration and decomposition of fibrin. The interaction between the organism and the micro-organism is the same as for, say, the streptococcus, the purpose of the reaction being localization of the infection, destruction of the micro organisms and restoration of the injured tissues to normal. Failure of the organisms to localize the infection results in spread and complications. In heat there exists the best means of increasing hyperemia, exudation and leukocytosis, and the Elliott machine is an excellent instrument to produce a constant high temperature in the vaginal cavity, an area fortunately tolerant to great heat.

Why should a constant high temperature be beneficial in inflammation elsewhere and contraindicated in acute gonorrheal endocervicitis? Dr Barringer's reason is that the cervix is softened and the natural barriers are opened to the spread of the infection. It seems incredible to us that the cervix should behave contrary to all other tissues, in response to heat. Heat is universally applied with benefit to localize infection, to seal tissue spaces and to prevent spread of infection. Her statement is contrary to our knowledge of inflammation and the value of heat as a therapeutic agent. It is true that the cervix is softened by the application of strong heat, but the softness is due to increased exudation and increased mucus secretions of the cervical glands.

Dr Barringer suggests gentle washing of the cervix and topical applications in acute gonorrheal endocervicitis. The cervix, being a glandular structure, harbors the gonococci deep in the glands, and the tissue reaction to this organism is ordinarily very weak. Surface applications are of but little value.

Intense heat is our only means to stimulate and augment the body's own defensive reaction to localize the infection and eradicate the gonococcus. We also wish to add that up to the present we have treated hundreds of cases of acute gonorrhea in the female entirely by the Elliott machine at a temperature of about 130 F without a single complication.

LEO MICHEL, M.D.,
NORMAN TAUBE, M.D.
New York

PINEAL GLAND

To the Editor —I have read with great interest the editorial on the pineal body (THE JOURNAL, Nov. 24, 1934, p 1626). My investigations (Zentralbl f Gynok 57:634 [March 18] 1933) have shown that my extract of the pineal body has an antiestrogenic effect, disturbs the estrous cycle, inhibits the development of weight in infantile mice, and has a therapeutic effect in certain genital bleedings, particularly cases of juvenile bleedings.

CHARLES BURGER, M.D. Budapest

ANALGESIA IN OBSTETRICS

To the Editor —What is the entire technic of producing analgesia in obstetric cases at the hospitals in and about Chicago? This includes I believe, the use of pentobarbital, scopolamine and in some cases apomorphine. Details would be appreciated.

ARTHUR CLAYTON MCCARTY, M.D. Louisville, Ky

ANSWER —There are a variety of methods and drugs in use in the hospitals in Chicago for the production of analgesia in labor. Opiates have stood the test of time and are probably the most useful drugs. They can be combined with other drugs, such as scopolamine or magnesium sulphate. The only real objection to the use of an opiate is the likelihood of narcosis of the infant, resulting in asphyxia. This danger is not very great, and asphyxia is not a common occurrence, especially if the drug is used with care at the right time in labor. An accepted technic is as follows:

In primiparas, after the pains have been well established—coming regularly every two or three minutes and lasting from thirty to sixty seconds—and when the cervix is partially effaced and the cervical os dilated to 3 or 4 cm in diameter morphine sulphate from 11 to 16 mg, or $\frac{1}{8}$ to $\frac{1}{4}$ grain, depending on the size of the woman (the smaller dose being used in small women), and scopolamine 0.4 mg, or $\frac{1}{150}$ grain, are given to the patient. The scopolamine may be repeated at the end of one hour 0.3 mg, or $\frac{1}{200}$ grain, if the patient has not had much relief. As a rule, following the initial hypodermic injection, the patient begins to doze between labor pains or will sleep for three or four hours. Progress is usually well maintained throughout this period of semiconsciousness, with labor well advanced when the patient is completely aroused from the effects of the analgesia.

A new opiate has been introduced recently in the form of dilauid (dihydromorphine hydrochloride). This drug has been used by several obstetricians and has been tried out in a large clinic with excellent results. In fact, in many respects this opiate gives more complete analgesia than morphine sulphate without apparent interference with the normal physiology of labor. One may use dilauid 2 mg, or $\frac{1}{32}$ grain, with scopolamine 0.3 mg, or $\frac{1}{200}$ grain, given about the same time as in the case just described. Dosages as high as 3 mg, or $\frac{1}{20}$ grain, have been recommended, but the smaller dose has been entirely satisfactory. In multiparas, either opiate may be given earlier in labor than in primiparas.

When dilatation is complete, analgesia may be provided by inhalation of nitrous oxide and oxygen or ethylene and oxygen during the pains. The mask is placed on the patient's face when the pain begins, and she inhales several deep breaths until the height of the pain is reached, and then as the pain subsides the mask is removed. Either gas may be given for as long as two hours without any danger to the patient. Drop ether likewise, may be used for analgesia during the second stage of labor. This is used with an open mask over the face during the pain and removed after it subsides.

Pentobarbital sodium has become popular recently for the production of analgesia in labor. It is given according to the following method: When labor is well established and the cervical os is dilated to 3 or 4 cm in diameter, 0.5 Gm, or $7\frac{1}{2}$ grains, in capsules may be given by mouth to the patient of average weight. In another twenty minutes the patient is given scopolamine 0.4 mg, or $\frac{1}{150}$ grain, hypodermically. The patient may sleep or only doze between pains, but the uterine contractions continue satisfactorily. Although she may not doze continuously during the analgesia, often she does not remember what has happened when labor has been completed, almost complete amnesia may be produced.

A host of other drugs have been recommended from time to time for analgesia in labor. Many of them are not satisfactory from the standpoint of interfering with the uterine activity, causing prolonged labor and resulting in operative intervention. Other drugs do not provide the degree of relief demanded by patients in labor. To be an ideal analgesic, the drug must not interfere with uterine motility. It must be safe for the mother and likewise for the baby.

Asphyxia of the baby resulting from morphine is best treated by inhalation of carbon dioxide and oxygen. Carbon dioxide may reach a concentration of 30 per cent in oxygen if it is

used for only a few seconds. The initial efforts at resuscitation are usually sufficient and this concentration of the gas may be followed by 5 per cent carbon dioxide in 95 per cent oxygen.

Apomorphine 2 mg., or $\frac{1}{160}$ grain, has been advised as a mild sedative. It is not satisfactory as an analgesic in labor.

Further details on narcosis and methods of resuscitation are given by Shute, Evan and Davis, M. E. *Effect on the Infant of Morphine Administered in Labor, Surg., Gynec. & Obst.* 57:727 (Dec.) 1933.

TIN OR LEAD POISONING IN INDUSTRY

To the Editor—A man aged 32 in excellent physical condition had had no serious illnesses and no gastro-intestinal complaints whatever until three years ago. At that time (his occupation being that of a mechanic) he was called on to do a soldering job which took nearly four days of continuous work and was done in a poorly ventilated room. The day on which the work was completed he suddenly became distended with gas, had severe abdominal cramps, suffered from constipation and vomited several times. He consulted a physician who treated him for several weeks during which time he became only moderately better and was finally referred to a specialist. Here he was given a complete gastro-intestinal series of roentgenograms including gallbladder visualization and a gastric analysis. All of these were negative. He was placed on a milk diet for over a month with no relief. Since that time he has had modified versions of the original attack with distention, abdominal distress and constipation about every three months lasting from a month to two months. In the intervals he is comparatively well. Physically he is of robust build and entirely negative to physical examination with only a moderate general tenderness to palpation throughout the abdomen. The Wassermann reaction, the blood both on count and smear and the urine are negative. The stool is negative to two examinations. Is there any possibility that lead or tin poisoning might have been contracted during his prolonged soldering job? Would not the milk diet have given him some relief had that been the case? Are there any suggestions as to diagnosis or further diagnostic procedure in this case? Please omit name and address.

V. D. California

ANSWER—Tin poisoning is always doubtful as an occupational disease entity. On the other hand, the possibility of lead poisoning is greater, but neither the circumstance of exposure nor the disease manifestations as described warrant any belief that lead poisoning took place. The development of a full blown lead poisoning on the fourth day of exposure to lead is not well preceded. If recent previous exposures to lead antedated this exposure period of four days lead poisoning becomes more of a possibility. Careful blood examination, including basophilic aggregation tests may be of some value. Single examinations of the urine or feces for lead are without distinct value since some lead normally may be present. The finding of stipple cells, low hemoglobin and low total red count would have some positive value but, of course are not conclusive. The development of lead poisoning from the fumes of molten lead is relatively much rarer than the causation of this disease by lead dust or lead paste. Cases of the character described are not infrequent among metal workers. Ordinarily they represent nonindustrial diseases that have been precipitated by exposure to mixed vapors and gases from heating units, from fluxes or from the metal itself, no one of which is capable of producing a characteristic disturbance in such operations as soldering or welding. Future diagnostic search should be directed to the ruling out of lead poisoning, decision as to which should not rest on any one or two tests but on complete examination of the blood, musculature, gum discoloration and so on.

HYPERTHYROIDISM

To the Editor—A white man aged 40 was diagnosed roentgenologically tuberculous around an old scar in the right apex. There is no cough or sputum. The afternoon temperature ranges from 99 to 99.2 F. Following two weeks in bed symptoms of muscular weakness and exhaustion, tremors, twitching, restlessness and insomnia are much worse. He has a very large normal appetite and during this time has lost about 5 pounds (2.3 kg.). His mind is clear and active but he is very depressed. The basal metabolic rate is +35. The thyroid is not tender or enlarged nor is there any exophthalmos. 1. With a questionable diagnosis of active tuberculosis, is iodine contraindicated? 2. With a positive diagnosis of a mild tuberculosis is iodine contraindicated? 3. Is high voltage roentgen therapy of more benefit than iodine? 4. If the patient should become a good operable risk would you advise vessel ligation or partial or total thyroidectomy?

JAMES S. MILLIKEN, M.D. Southern Pines, N. C.

ANSWER—On the facts stated, the illness of this patient is in all probability hyperthyroidism. The scar at the right apex disclosed by roentgen examination may be due to an old pulmonary or pleural infection long since healed and of no clinical significance in the present illness. It is of course remotely possible that hyperthyroidism and tuberculosis exist together, but in this event it is certain that such tuberculosis as is present is playing but a minor part in the production of symp-

toms. Loss of weight in the presence of a good appetite, while highly suggestive of hyperthyroidism, should also suggest the examination of the urine to exclude diabetes mellitus.

1. The use of small doses of iodine is indicated. The probable favorable effects on the hyperthyroidism far outweigh the remotely possible ill effects on the minimal and probably inactive scar at the right apex.

2. With a positive diagnosis of mild tuberculosis (in which case more evidences of active tuberculosis would be required than are here given) the use of iodine would raise serious questions. It is believed by many clinicians that iodine favors the absorption of scar tissue, especially in granulomas, and that tuberculosis which heals by scarring and encapsulation of tuberculous lesions is unfavorably affected by iodine.

3. Roentgen therapy has been used extensively in hyperthyroidism, with many favorable results. In most cases iodine, followed by appropriate surgical treatment, is at present preferred to roentgen treatment. In a number of mild cases of hyperthyroidism, iodine therapy is sufficient.

4. After adequate treatment with rest, a full diet and iodine, surgical measures may also be necessary. The choice of operative procedures will depend on the condition of the patient. In marked cases of hyperthyroidism, subtotal thyroidectomy is usually recommended. Ligation of vessels alone is sometimes done, usually in severe cases in which a more extensive operation cannot safely be done or as a preparation for later resection of the gland.

DIAGNOSIS OF ALLERGY

To the Editor—A well nourished and well developed girl aged 15 years who comes from a definitely allergic family developed facial impetigo contagiosum about ten weeks ago. A standard prescription of dilute aluminum subacetate soaks was ordered, to be followed byunctions of 10 per cent ointment of ammoniated mercury. In a few days the child's face became uniformly swollen and the vesicular and pustular impetiginous lesions became bullous. The mercury ointment was stopped and boracic acid soaks substituted for the solution of aluminum subacetate and calcium lactate and ephedrine by mouth were instituted. The bullous lesions gradually subsided and the edema slowly disappeared but there followed a series of angioneurotic explosions which have persisted to date. On one occasion both buttocks became symmetrically indurated and swollen with a picturesque gyrate border extending down both thighs and legs. Then giant hives appeared and disappeared. Succeeding crops of hives were smaller in individual size and of shorter duration. When it appears as if the explosion is dying out the next event is swelling of the extremities or one side of the face. An intercurrent otitis media developed following a mild nasopharyngitis which required paracentesis. About half an hour following the administration of ethyl chloride by inhalation the lips and face became markedly swollen. This attack lasted about ten hours. The physical examination is otherwise negative. The blood picture, Kahn reaction, phenolphthalein test and urinalysis are normal. A competent dentist has ruled out dental infection. The tonsils are out clean. I did a series of scratch tests without any positives. Incidentally the scratch marks produced only a slight amount of residual dermatographism. What additional procedures would you advise in an effort to get at the bottom of this case? Please omit name.

V. D. Michigan.

ANSWER—Apparently there are two separate stages in this case. The first event was a dermatitis, possibly due to sensitivity by contact. The second stage consists of a series of superficial and deep forms of urticaria. This phase is more likely due to an internal source of sensitization. It is difficult to account for the sequence of these two stages. It is possible that the inflammation of the skin has allowed the entrance of products, particularly bacterial or fungous, into the body so that subsequent exposure to organisms (respiratory, intestinal) may cause an allergic flare-up. Contact causes foods and bacterial sensitization must therefore be considered.

To determine the factors responsible for the dermatitis, ordinary scratch tests are usually of no value. One must do a series of patch tests. A small piece of the material is placed on a separate piece of gauze about an inch square. If the material is dry it may be moistened with liquid petrolatum. This "patch" is applied with the testing material next to the surface of the skin. The gauze is then covered with a square of oiled silk and fastened to the skin with adhesive tape. Several patches may be applied to the back at one time and examined after from twenty-four to forty-eight hours. A positive reaction will consist of itching and redness, if more severe going on to edema and vesiculation. In the case cited one would have to test in this manner the chemicals that had been used, the ointment base, wool, cotton and silk.

In addition to the foregoing the cause of the urticaria will probably require further search. The scratch tests should be as complete as possible and if all are negative they should be tried further by the intradermal method. In the event that the latter are negative one may still assume that a food may

be the cause of the urticaria. Experimental diets such as elimination diets described elsewhere are in order (Feinberg, S M Allergy in General Practice, Philadelphia, Lea & Febiger, 1934 Rowe, A Food Allergy, Lea & Febiger, 1931) If foods are not found to be at fault, a more thorough search for infection must be made—intestinal, gallbladder and so on. At times the basal metabolic rate is found to be lowered.

SCROTAL TONGUE

To the Editor—In my clinical experience over many years I have often seen furrowed or scrotal tongues of varying degree in apparently normal persons. They have caused me to wonder what causes such a tongue. My first chronic case was a cretin whose tongue was deeply furrowed and scrotal in appearance. He responded well to thyroid treatment but his tongue never changed. His father had a medium scrotal tongue but was not a cretin. I have seen many such tongues in apparently normal persons but have never seen any opinion expressed as to the probable cause. In more recent years, since studying endocrinology and its relation to subacute and chronic arthritis I have found that the scrotal tongue is quite common in women and a few men, who are generally suffering from hypothyroidism. I have noticed these patients improve on liberal doses of thyroid. I have been looking on these scrotal tongues as cases of hereditary hypothyroidism. I saw one woman aged 30 who has suffered for years from chronic rheumatoid arthritis in her hands, knees and feet. She went through a normal pregnancy and confinement and gave birth to a normal child that does not show a scrotal tongue. She was on thyroid, 1 grain (0.065 Gm) twice daily, during her pregnancy. Her mother shows a medium scrotal tongue and has a mild case of rheumatoid arthritis. I should like your opinion as to the cause of scrotal tongue.

F A BOOTH MD Seattle

ANSWER—Scrotal tongue (lingua plicata) is usually congenital and often familial. The tongue is nearly always larger than normal, the enlargement may be very marked. Milder forms of furrowed tongue are fairly common. The condition is permanent and of no special significance except when food particles collect in the crevices and cause irritation, which, if recurrent, may predispose to epithelioma. There is no evidence that hypothyroidism is an etiologic factor. An acquired form of grooved tongue may follow various forms of glossitis or be due to other disease, notably syphilis. Oversize of the tongue may predispose to the formation of sulci or may aggravate the condition. In marked thyroid deficiency (myxedema and cretinism) the tongue is large and thick but it rarely shows the fluted appearance characteristic of the scrotal tongue. If treatment of the hypothyroidism is neglected or ineffectual, the chronic enlargement may predispose to the appearance of grooves. Otherwise there is no recognized connection between hypothyroidism and the scrotal tongue.

DOUBTFUL DIAGNOSIS OF SYPHILIS

To the Editor—A white man, aged 34, married has been under my care. In 1918 complicating a severe attack of influenza the patient developed bronchiectasis. At present he expectorates from one-half to 1½ ounces of purulent sputum each twenty-four hours. An injection of iodized poppy seed oil in 1926 revealed a bilateral bronchiectasis. Laboratory examination of the sputum revealed spirochetes and negars phenamine was given 0.3, 0.45 and 0.45 Gm at weekly intervals. The third dose of 0.45 Gm caused a slight reaction and the drug was discontinued. In 1924 the blood Wassermann and Kahn reactions were negative. The patient was married in 1930. In February a year later one morning following coitus he noticed a small reddened macular area the size of a pea on the corona. Three weeks later a blood Wassermann reaction was Kolmer 3 plus Kline negative. Neosaphenamine was begun and 0.3 0.45 0.6 0.45 0.45 and 0.45 Gm were given at weekly intervals. Between the sixth and seventh injections Kolmer and Kline reactions were negative. There was a slight reaction to the 0.6 Gm. dose, so that is why the 0.45 Gm. doses were continued. The reports on Kolmer and Kline tests were negative for a month afterward then the Kolmer became 2 plus again with a negative Kline. At the same time a sample of the same blood was sent to another laboratory and the report was a negative blood Wassermann reaction and negative Kahn. The blood reports have been negative with no treatment until two weeks ago when a report of a blood Wassermann reaction was + and Kahn negative. The Kline and Kahn reactions have always been negative with a marked variation in the Kolmer and Wassermann, at two different laboratories. There is no history of outside exposure and repeated blood tests on the wife have been negative. There has never been any clinical evidence of syphilis except the atypical lesion mentioned. Recently there has been noticed a scaly appearance over the site of the old lesion but it does not look like a syphilitic condition. Please tell me whether or not this is syphilis if it is outline the course of the treatment. Would you advise spinal puncture? Please omit name.

M D South Carolina.

ANSWER.—This is an excellent illustration of the danger of treating a patient for syphilis without having an absolutely definite diagnosis. The basis for the original diagnosis on which treatment was instituted was hardly adequate for a diagnosis. No examination for spirochetes having been made, one cannot say whether or not the lesion described was of syphilitic origin. With only one Kolmer type of Wassermann reaction

positive, and a negative Kahn, one cannot eliminate the possibilities of error and, following the treatment that he received, might conceivably have been sufficient to change the reaction in the case of syphilis, although this is not too likely. The subsequent results are confusing but by no means definitely indicative of syphilis. The fact that the wife shows no signs of syphilis makes it extremely doubtful that the original lesion was of syphilitic nature. One can only have a conjecture about the case, which is that the man probably has not had syphilis.

The procedure that would seem wise would be to have about a dozen tests made in succession in a reliable laboratory. This would give one a pretty good indication of the present condition. If the tests are uniformly negative with a sensitive test such as the Kline test well carried out, and if this is backed up by negative Kahn and Wassermann tests, one would have justification for feeling that no further treatment is indicated, although rechecking at intervals of six months to a year would be a reasonable procedure.

If for any reason one is not thoroughly satisfied that the results of the tests show the absence of syphilis, treatment should be vigorously given for a period of a year.

DERMATITIS IN ENGRAVING INDUSTRY

To the Editor—I recently saw a white man aged 50 a printer who has been working in the engraving department during the past two months using a fine aluminum dusting powder which at the end of the day's work covers his face and hands and is inhaled into his mouth and nostrils. Recently there have developed about his face scalp chest, back and arms isolated bright red protruding petechial lesions varying from a pinhead to a lentil in size and about a dozen in all. There are no other symptoms and the lesions themselves are symptomless. When one ruptures there is protracted bleeding one having bled an hour and a half according to the patient's statement. A crust then formed but the lesion does not vanish but may later bleed again. There is slight induration about some of the lesions that have previously ruptured. The first lesion was on the eyelid and was cauterized by a physician. The patient feels generally well. Never better in my life he states. No other hemorrhagic manifestations have been noted and the past history is negative. Examination is essentially negative except for the lesions which are confined to the areas described and are not found elsewhere. The patient had a slight fever 99.4 F when the first time in my office. The pulse was 76 respirations 18 and the blood pressure 130 systolic, 90 diastolic. His height is 5 feet 6 inches (167.6 cm.) his weight 153 pounds (69 Kg). He has several carious teeth but the gums do not appear abnormal. There is no lead line or hemorrhagic area. Stereoscopic views of the lungs were negative. Laboratory study of the urine gave negative results. A stool specimen was strongly positive for occult blood. The Wassermann reaction was negative. The bleeding time was one minute. The coagulation time was three minutes. Blood examination revealed red blood cells 5,460,000 hemoglobin 105 per cent white blood cells 13,150 of which 30 per cent were small lymphocytes 4 per cent large lymphocytes and 63 per cent polymorphonuclears. Platelets numbered 121,000. A recheck on the blood study after two days made by a second laboratory differed slightly from the first and was as follows: red blood cells 5,120,000 hemoglobin 90 per cent, white blood cells 6,400, polymorphonuclears 69 per cent lymphocytes 26.5 per cent monocytes 2.5 per cent eosinophils 2 per cent. The platelet count was reported to be normal. In your opinion might this condition have been related to the patient's occupation either as an engraver using the aluminum powder or in his occupation as a printer in contact with various printers' inks or lead? His employer informs me that the powder which the patient has been using during the past two months and in which time these lesions have appeared is a fine aluminum powder and contains no other metal. Please omit name.

M D California.

ANSWER.—The aluminum powder described in this query has proved to be almost innocuous in the causation of any occupational disorder, although a number of spurious claims have been made alleging various forms of damage. Occasionally enough lead is present as an impurity in the aluminum to result in a diagnosis of lead poisoning as the result of exposure. The dyes used for the making of colored metallic dusting powders have been regarded with suspicion as a source of dermatitis. Local mechanical action has occasionally led to lesions about the face. The dermatosis described may not readily be attributed to the action of this aluminum powder. If of occupational origin at all, greater significance perhaps is to be attributed to other substances used in the engraving and print shop such as various inks, glues for binding aluminum bronzes, and distillates employed in the cleaning of presses and type. However it is not known that this type of lesion may be ascribed to any of the substances contemplated. Some benzene may be used for cleaning purposes and in glues used in printing establishments but the results of the blood examinations seem to rule out the likelihood that this hemorrhagic nodulation may be attributed to benzene or related substances. It is quite within reason to believe that disturbance of nonoccupational origin might be aggravated by dusty and liquid substances found about a printing plant, but no warrant is known to exist to lay the blame on work as the primary cause.

Without attempting any diagnosis, the suggestion is made that this disorder may be of the character of an erythema nodosum or at least one of those entities similar to erythema nodosum. Also there exists the possibility that the lesions may represent the invasion by fungi or other vegetable parasites, cases of which are appearing with a fair frequency at this time.

CARCINOMA OF THE APPENDIX

To the Editor—Recently my wife aged 22 developed acute appendicitis and appendectomy was done. Gross examination of the appendix at the time of removal showed acute inflammation with congested serosa of the distal third. A specimen was sent to the laboratory for further study. Laboratory diagnosis was that of carcinoid appendix with invasion into the muscle and extending to the serosa with small invasion into the meso-appendix. The carcinoid had blocked the lumen of the appendix in the proximal third and also there was present an acute inflammation. What are the possibilities of malignancy and what treatment if any would you suggest be instituted? Please omit name. M D Ohio

ANSWER—Carcinoid tumors of the appendix are differentiated microscopically from carcinomas of the appendix in that the former contain (1) strands or cords of argentaffine cells, (2) few mitotic figures, and (3) an alveolar but never glandular arrangement of cells. Carcinoid occurs usually before the third decade in contrast to carcinoma, which is most common after the third decade. More than 92 per cent of carcinoids occur in the distal half of the appendix, while carcinoma of the appendix is usually found in the proximal portion and is primarily from the cecum. These facts are consistent with the diagnosis of carcinoid in the case in question.

The reported evidence on this subject indicates that, in appendices removed for appendicitis per se 0.46 per cent are found to contain carcinoid tumors, and that from 2 to 6 per cent of these cases may show evidence of malignancy, such as extension, metastasis or surrounding glands or recurrence.

Surgery usually suffices to cure this condition. Being of neurogenic origin, these tumors are probably resistant to radiation although a preliminary review of the literature fails to reveal any data on the radiotherapy of this condition. If careful gross and microscopic study of the removed specimen indicates that the excision extends outside the area of disease, a cure has in all likelihood been effected. The age of the patient and the probable radioresistant nature of the lesion contraindicate any form of radiotherapy in this case. On account of the chances of malignancy being so small, a second surgical procedure is contraindicated.

EFFECTS OF PHENOL ON TYMPANUM

To the Editor—Several months ago I heard a story about an intern who once injected subcutaneously pure phenol in place of procaine which he had really intended using. I little realized that I could be guilty of such absent mindedness. Intending to instill several drops of a 5 per cent phenol-glycerin solution into an external auditory canal which I had just cleaned of impacted cerumen. I squirted instead several drops of pure phenol into the ear. The patient of course immediately complained of a severe burning sensation in the canal but it was not until about one and one-half or two minutes later that I realized the stupidity of my error. I quickly syringed out the canal first with warm water followed by an abundance of 70 per cent alcohol. This gave the patient some relief and a few minutes later I instilled several drops of the 5 per cent phenol-glycerin solution in the patient's ear. I then gave him a prescription for this solution and advised him to use several drops in his ear three times daily. Before the phenol was inserted I had noticed that the drum was intact. After washing out as much of the phenol as I could I inspected the drum which fortunately was still intact but the outer lining of the drum was of a dull white color and there was no glistening appearance. I have not seen the patient again as yet. Will you tell me whether the drum will become necrotic? Will the hearing in this ear become affected? What subsequent treatment would you advise? Please omit name. M D New Jersey

ANSWER.—The application of a concentrated phenol solution to the drum membrane causes the epithelium to become white just as it does if applied to the epidermis, elsewhere. The use of alcohol immediately after the accidental use of the pure phenol probably stopped its caustic action. It is quite likely, therefore that there was complete recovery, and no destruction of the drum membrane itself and no perforation.

It is certain that if only the surface of the drum membrane was involved no impairment of hearing took place. There was no subsequent treatment that could have been applied. If there was only a superficial involvement of the drum membrane, even if the patient had been seen directly after, no special treatment would have been necessary. If there had been prolonged action of the phenol with any necrosis of the drum membrane nothing could have been done except the use of alcohol or oil at the time.

Nevada November Examination

Dr Edward E. Hamer, secretary Nevada State Board of Medical Examiners, reports the written examination held in Carson City Nov 5, 1934. The examination covered 11 subjects and included 110 questions. An average of 75 per cent was required to pass. Three candidates were examined, all of whom passed. Two physicians were licensed by reciprocity after an oral examination. The following schools were represented:

School	PASSED	Year Grad	Per Cent
Maryland Medical College	(1906)	82.1	
St. Louis University School of Medicine	(1925)	76.7	
Jefferson Medical College of Philadelphia	(1918)	82.6

Book Notices

An Introduction to Gynecology. By C Jeff Miller M.D. Professor of Gynecology Tulane University School of Medicine. Second edition. Cloth. Price \$6. Pp 354 with 121 illustrations. St. Louis: C. V. Mosby Company, 1934.

No teacher of gynecology can be expected to be completely satisfied with any single gynecologic textbook unless perchance he has written it himself. Over a period of years the author carefully sifted out from a number of sources the data best suited to his own methods of teaching. He has collected and organized these data. In the review of the first edition in THE JOURNAL it was regretted that Miller has so frequently borrowed in preference to drawing from his own broad sources. There is room here for a difference of opinion. Miller has done well to use for his teaching needs the instrument best adapted regardless of source. Never with any thought of self aggrandizement, his tone is consistently simple, unassuming, modestly and helpfully instructive. The text is completely shorn of non-essentials. Elimination of personalities, fads and fancies gives it an enviable consistency and an even distribution of subject matter. There is no topheaviness and unevenness begotten of personal hobbies and axes to grind. The book is far from striking in its immediate effect. It presents, for the most part, fundamental run-of-the-mill teaching gynecologic material. It may well be said that its chief virtue lies rather in its manner of presentation than in any conspicuous virtue or originality in its intrinsic makeup. Objection has also been raised to the lack of originality in the author's selection of illustrations. This objection should be flatly overruled in view of the consistent selection of good illustrations. Cuts of time proved value, some even of hackneyed old favorites, offer clear proof of the unostentatious devotion to the art of gynecologic teaching. Much is to be said for those who have sufficient insight to realize that the teaching of gynecology may best be approached from a number of different angles. Some reviewers have lamented the absence of simple fundamental gynecologic concepts in more advanced textbooks and reference works, others signalize the failure of such fundamental works as Miller's to present advanced research phases, surgery and the clinical technique of treatment. The trend toward separation of the various phases of this broad subject is an excellent one. There can be no question that the segregation of this material for teaching purposes is rational. Certainly by comparison Miller's book seems rather brief, perhaps elementary, yet if a student will assimilate a reasonable proportion of its sound teaching he will have obtained an adequate grounding for later research and the building of clinical knowledge—and without the grinding ordeal of sorting out for himself what is essential to this fundamental grounding. Miller offers a simple but nourishing diet for the student's mental digestion, a digestion not trained to discretion in the selection of a sufficiently simple fare for its own consumption.

Schistosomiasis (Bilharziasis). By Dr Rameses Girges. With a foreword by Professor Ernest Carroll Faust. Cloth. Price 25s. Pp 529 with 185 illustrations. London: John Bale Sons & Danielsson Ltd. 1934.

This volume represents the most complete single account of schistosomiasis now available. There are ten parts each with from one to six chapters. Part I is an introductory historical account of the development of the present knowledge of schistosomiasis. Part II deals with the parasitology of the family Schistosomidae. Part III gives a summary of the present geographic distribution and the factors in the epidemiology of the human types of the disease. Part IV is a useful compendium of practical methods for the study of the parasites, including a description of the molluscan intermediate hosts. Of particular interest from the medical standpoint are parts V, VI, VII and VIII which deal with schistosomiasis haematobium, schistosomiasis Mansoni of the intestinal type, schistosomiasis Mansoni of the visceral type and schistosomiasis japonicum, respectively. Under each infection a careful outline is given of the pathology, clinical aspects, prognosis and treatment, both medical and surgical. The division of schistosomiasis Mansoni into intestinal and visceral types is of particular interest. The intestinal type is the orthodox, clinical picture ascribed to

Manson's schistosomiasis The visceral type is the syndrome of hepatic cirrhosis, splenomegaly and ascites, which is generally termed Egyptian splenomegaly and is usually considered of unknown etiology. The author has collected a tremendous series of clinical, pathologic and parasitologic data indicating that this disease is due to unisexual infections with the male *Schistosoma* Manson. The male cercariae reach the liver and grow to maturity but, finding no females or an insufficient number, do not migrate to the mesenteric region, where oviposition usually occurs. In the meantime their presence in the liver incites an immunity which prevents the development of female cercariae even if these are later acquired by the patient. The fact that this condition is a schistosomiasis has been missed largely because there are no eggs found in the feces or urine. Part IX is a general survey of specific treatment and emphasizes the great advances made since the introduction of the antimonial preparations. Part X gives a short discussion of prophylaxis. The author has had an amazing contact with clinical cases of the Manson and haematobium types of the disease, and the book is the result of this experience plus a very thorough biologic grounding. The book is well written and illustrated and will be indispensable to all clinicians, sanitarians and parasitologists interested in this group of trematodes. It is to be regretted that the author compiled no extensive bibliography, although frequent references are cited throughout the text.

Diseases of Women By Ten Teachers Under the Direction of Comyns Berkeley M.A. M.D. M.C. Obstetric and Gynecological Surgeon to the Middlesex Hospital. Edited by Comyns Berkeley J. S. Fairbairn and Clifford White. Fifth edition. Cloth. Price \$6. Pp. 508 with 193 illustrations. Baltimore: William Wood & Company 1934.

Peculiarly enough this book though written by ten different men, possesses remarkable consistency. It is thoroughly reliable, well grounded in authority, and consistently solid (almost stolid). It is thoroughly British in its devotion to unenlightened detail—a virtue, no doubt in an academic teaching textbook. Blunt British parlance brings forth apt expressions such as "slop diet" for "soft diet," "plugging" the uterus for "packing," and "enquiry" instead of "inquiry," with a liberal smattering of diphthongs. No method is superior for teaching purposes to that used in this work. The orderly presentation of etiology, pathology, symptoms, diagnosis, treatment and prognosis is exemplary. Granting the value of such orderly sequence, one is surprised to note a lack of balance in the total consideration allotted to various general subjects. Ectopic pregnancy for example and uterine fibroids are treated in great detail (except for micropathology). An exhaustive reference work could hardly be expected to contain a more adequate presentation of either subject. In sharp contrast are the sections on gross anatomy and physical examination, which are meager. A similar unevenness of distribution is obvious in the use of illustrations which are in general good. The color cuts are well chosen but a bit florid. Consistently excellent throughout this work is the consideration of differential diagnosis. Specialist, clinician and student will profit by careful study of such sections. Revision and additions to the section on menstruation and endocrine influence call for favorable comment. The section on retroversion, particularly in relation to treatment, is sound and helpful. The section on the pathology of prolapse is excellent. A subject ordinarily difficult is here presented in lucid sequence. Conservative treatment is given almost more than its fair share of consideration. The rationale of operative care is well presented. Unfortunately, the procedure described for the control of prolapse does not seem to meet the broad indications laid down in the section on underlying pathology. Micropathology is skimmed, purposely, no doubt. The discussion of acute salpingitis leaves the reader with the definite impression that the author favors early operation. An obvious effort is made to straddle the issue yet the conviction remains that the author agrees with the authorities who hold that the best treatment of salpingitis is to operate in the early stage of the attack, as in appendicitis. In the present status of our actual knowledge this wavering position seems totally indefensible. Out of charity one must suppose that this section has been overlooked in the revision of material for this edition. In spite of minor flaws this must be regarded as an excellent textbook of more value in academic teaching than in clinical practice of considerably more value in fact in this teaching field than many of its sur-

facely more brilliant contemporaries. In general a thoroughly sound and reliable work, it can be highly recommended for the teaching of basic gynecology to undergraduates.

Einfache quantitative, klinisch chemische Harn und Blutuntersuchungsmethoden. Eine Anleitung zur Ausführung diagnostisch wichtiger quantitativer Methoden ohne besondere Laboratoriumseinrichtung zum Gebrauch für die ärztliche Praxis. Von Prof. Dr. med. et. phil. Erwin Becker, Oberarzt der Medizinischen Universitätsklinik Frankfurt a. Main. Mit einem Vorwort von Prof. Dr. F. Volhard, Direktor der Medizinischen Universitätsklinik Frankfurt a. M. Paper. Price 7.50 marks. Pp. 163 with 7 illustrations. Jena: Gustav Fischer 1934.

This is a compilation of the clinical and chemical methods for the investigation of diseases of the kidney, gallbladder and liver. For the most part the book deals with renal disease, and only a small but adequate section is devoted to the gallbladder and liver. The author has been closely associated with Volhard through practically all his work on renal disease and is well equipped both from experience and from training to present an authoritative treatise on this subject. While the work is essentially in manual form, the thoroughness with which the data are handled compares favorably with more exhaustive books on the subject. The reader further has the advantage of the author's extensive experience in not having to decide as to the value of any of the methods given. Only such procedures as have been definitely proved helpful clinically are discussed. An English edition of this book should be well received by the profession, as it is only by the application of such procedures that the subject of nephritis will become clarified. The manual should prove to be of great value to those who are interested in diseases of the kidney and liver and to those who would like to extend their information to the laboratory phases of the subject. The laboratory worker will also find this work an authoritative and explicit laboratory manual. The book is highly recommended to both.

Studies in Asphyxia. I. Neuropathology Resulting from Comparatively Rapid Carbon Monoxide Asphyxia. II. Neuropathology Resulting from Comparatively Slow Carbon Monoxide Asphyxia. III. Neuropathology Resulting from Comparatively Slow Carbon Monoxide Asphyxia Reaction During 10 to 105 Days After Exposure. IV. Neuropathology Resulting from Comparatively Rapid Asphyxia by Atmospheres Deficient in Oxygen. V. Blood Chemistry Changes Resulting from Comparatively Rapid Asphyxia by Atmospheres Deficient in Oxygen. VI. Blood Chemistry of Dogs After Comparatively Rapid Carbon Monoxide Asphyxia. By W. P. Tait, John Chornyak, H. H. Schrenk, F. A. Patty and R. R. Savers. Prepared by the Direction of the Surgeon General, U. S. Treasury Department, Public Health Service. Public Health Bulletin No. 211. Paper. Price 15 cents. Pp. 61 with 86 illustrations. Washington, D. C.: Supt. of Doc. Government Printing Office 1934.

This bulletin of the Public Health Service presents in brief form a thorough study of the neuropathology resulting from (a) rapid, (b) slow and (c) long continued carbon monoxide asphyxia (d) the comparable neuropathology of rapid asphyxia by atmospheres deficient in oxygen but containing no carbon monoxide and the blood chemistry changes resulting from (e) rapid asphyxia by simple anoxia and (f) those induced by rapid carbon monoxide asphyxia. Photomicrographs of sections of the brains of asphyxiated dogs and rats are reproduced. Two types of degenerative changes were observed in nerve cells, some becoming shrunken and staining diffusely others showing varying degrees of chromatolysis. In dogs these changes occurred chiefly in the cells of the cerebral cortex in the corpus striatum and other basal ganglia. In rats the cortex was much less injured. In both species of animals, vascular changes were marked: dilatation of small blood vessels, stasis and perivascular hemorrhages. Edema occurred throughout the brains with infiltration of leukocytes particularly in the meninges. The principal changes in the chemistry of the blood were decreased oxygen content, decrease both of the content of carbon dioxide and of the carbon dioxide capacity, and a lowering of pH . The effects of asphyxia by simple oxygen deprivation and by 0.6 per cent carbon monoxide in otherwise normal air were essentially similar. None of the changes in the blood were such as would not be readily corrected when the anoxemia was relieved by treatment with oxygen or a mixture of from 5 to 7 per cent of carbon dioxide in oxygen. It is therefore apparent that the neuropathologic changes in the blood are not primarily responsible for the failure of moribund cases of carbon monoxide poisoning to respond to such treatment; the neuropathologic alterations initiated by profound and prolonged asphyxia are not reversible.

For the literature of the subject the reader is referred to a previous publication (Public Health Bulletin 195, 1930). Further observations on asphyxia are to be reported in a later publication, which would benefit from a closer correlation between the appearance and behavior of the subjects of the experiments and the structural and chemical changes than has been attempted in the present, otherwise excellent, article.

Étude sur le vibrion cholérique *Vibrio cholerae typus épidémique et Vibrio cholerae typus endémique* Par le Dr W. Doorenbos M.D. directeur du Laboratoire de Chatby du Conseil Sanitaire Maritime et Quarantenaire d'Égypte à Alexandrie. Paper Pp 120 Alexandria Société de Publications Egyptiennes 1934

The epidemiology of cholera, as relating particularly to pilgrimages of the local region, is considered in the light of observations on the serologic and cultural characters of *Vibrio cholerae*, bacteriophage, bacterial variation and host factors. From carriers, the author isolated strains of *vibrio* having characters unlike typical epidemic strains but similar to variants obtained in the laboratory by bacteriophage action. He advances the proposition, therefore, that bacteriophage in the intestine induces the appearance of *vibrios* capable of maintaining the endemic type of cholera. This is the role of the chronic carrier, who should be controlled because avirulent strains may be converted under certain conditions to virulent epidemic forms.

Practical Obstetrics for Students and Practitioners By P. Brooke Bland M.D. Professor of Obstetrics Jefferson Medical College Philadelphia and Thaddeus L. Montgomery M.D. Associate in Obstetrics Jefferson Medical College Philadelphia. Second edition. Cloth. Price \$8. Pp 730 with 516 illustrations. Philadelphia F. A. Davis Company 1934

In this handy volume a great deal of practical obstetric knowledge is condensed. In this edition the work has been brought down to date, preventive obstetrics being particularly emphasized. The book presents mainly the principles and practice of obstetrics of the Jefferson Medical College of Philadelphia. Naturally there is much in it with which one will not agree, but the personality of the book needs no defense. After a clear cut description of the anatomy and physiology of the reproductive organs the physiology, pathology and treatment of pregnancy are fully presented, then the physiology, pathology and treatment of labor, and then the complete story of the puerperium followed by operative obstetrics. Would it not present to the student, for whom this book is mainly intended, a clearer conception of the whole subject if at first he was given a complete rounded picture of a normal pregnancy, labor and puerperium? Then the aberrations of pathologic pregnancies, labors and puerperia would be more readily recognized and absorbed in the mind. For example, the treatment of abruptio placentae is given before the student knows how a normal placenta is expelled and the use of a bag in placenta praevia is shown before he is told how a cervix dilates during labor. The mechanism of labor is not as well described as its importance deserves. No mention is made of the work of Sellheim. The diagnosis and treatment of the pathologic presentations are good, the one adequate the other conservative and practical. More value is attached to prenatal pelvic mensuration than recent experience would justify. Caldwell's and Molloy's classification of the pelvic forms deserves mention in the next edition. Indeed, this may be said of several deficiencies and errors in giving credit for various procedures. A careful search through the literature for original sources is the only safeguard against such oversights. The puerperal hemorrhages are given brief and clear exposition and the chapter on puerperal infections is concise and adequate. The therapeutic nihilism expressed is disappointing but concordant with fact, and the conservative attitude toward local intervention is commendable. A short chapter on anesthesia and one on repair of injuries precede the presentation of operative obstetrics. The classic cesarean section is given undue prominence in view of the fact that its mortality in Philadelphia is five times that of the low cervical operation. A chapter on obstetric jurisprudence closes the book. The references are grouped in an appendix under the title "Referred Reading." The illustrations, twenty-one in colors, are good. Many are diagrammatic and a considerable number are original. The publishers have not spared expense in producing a handy, good looking and readable volume.

Entomological Studies *Studies in Insects of Medical Importance in South Africa* By Botha De Meillon D.Sc. F.R.E.S. from the Malaria Research Station of the South African Institute for Medical Research at Transvaal. Publications of the South African Institute for Medical Research No XXXIII (Vol VI) Paper Pp 249 308 with 14 illustrations. Johannesburg: South African Institute for Medical Research 1934

This contribution to medical entomology consists of detailed and highly technical reports on the first part of a series of notes on South African Simuliidae and descriptions of a new flea from the Transvaal belonging to the genus *Xenopsylla*, a new variety of *Anopheles natalensis*, the eggs of some South African anophelines, and the pupae of some heretofore undescribed South African anophelines.

The Human Body Its Structure and Activities and the Conditions of Its Healthy Working By H. Newell Martin. Twelfth edition revised by Ernest G. Martin. Professor of Physiology in Leland Stanford Junior University. Cloth. Price \$4. Pp 701 with 167 illustrations. New York: Henry Holt & Company 1934

This has been a standard textbook in American colleges for fifty years and has been for many students the avenue of introduction to anatomy and physiology. The present edition like the three preceding it, has been revised and edited by Ernest Gale Martin. The revision has dealt especially with subjects on which scientific growth has been rapid in recent years. The section on histology has been revised, the chapters on cerebral function and nervous conduction have been rewritten, the chapter on hormones is new. The work as revised maintains the standard set for earlier editions by Prof. H. Newell Martin. Since the publication, Dr. Ernest G. Martin has died. This edition constitutes a monument to these two great teachers of physiology.

Vegetable Drugs of India By Deraprasad Sanyal L.M. & S. Lecturer on Medical Jurisprudence and Rasbehari Ghose M.B. D.T.M. & H. Lecturer on Pathology and Bacteriology. Second edition. Cloth. Price, Rs 4/8. Pp 580. Calcutta: S. Chatterji. The Medical Publishers 1934

This book on the East Indian *materia medica* discusses the more modern views on the vegetable drugs alongside the uses the ancient Hindoo physicians made of them. The drugs are classified according to the system of the human body on which they chiefly exert their therapeutic action. One looks in vain for such drugs as digitalis, opium, cinchona or *nuxvomica*; the book being avowedly devoted to the native drugs of India among which one meets many to us well known with still more of them with which we are not familiar. One naturally wonders in view of this specialization to the vegetable drugs of India to what reading circle this book is addressed. If it is to be used as the principal book on *materia medica* in the teaching of medical students or if it is to serve as the guide in the selection of his remedy by the practicing physician, this exclusion of many of the most important remedies known to man is certainly objectionable. If this is the case, one must interpret this book as a manifestation of a nationalism so intense as to sacrifice the interests of the sick to the dictates of chauvinism; but this omission does not make the work any less interesting or useful as a reference work to the native drugs of India with which it deals.

Ergebnisse der experimentellen Krebsforschung und Krebstherapie von Dr. Ferdinand Blumenthal. Professor an der Universität Belgard. Paper. Price 4.25 H. florin. Pp 183. Leiden: A. W. Sijthoff's Uitgeverijmaatschappij N. V. 1934

The author is the former director of the cancer institute of the University of Berlin and for sixteen years he was the general secretary of a central committee (now dissolved) for the investigation and control of cancer in Germany. Being an active investigator he is well qualified by training and experience to review the advances in our understanding of cancer and its treatment and control since the beginning of the experimental era in the investigation of cancer at the dawn of this century. The book is divided into twenty sections. There are no illustrations. At the end are 497 references which are cited by numbers in the text. Unfortunately there is no subject index, but in its place is a detailed table of contents. Among the topics may be mentioned the definition and genesis of cancer, the relation of parasites, tar, the roentgen ray, irritation, trauma and heredity to cancer, precancerous conditions, the problems of the Rous sarcoma and the principles of the treatment of cancer.

by operation and by radiation. The final section is devoted to a review of organized efforts to control cancer through education of the public and of physicians and the setting up of fully equipped cancer centers. The book gives a concise but thorough and competent review of the progress of investigations of fundamental cancer problems, of the principles of modern treatment, and of the trends of the efforts to control cancer. It contains in condensed form a vast amount of information of value to the study of cancer.

The Principles of Therapeutics By Francis Richard Fraser M.A. M.D. F.R.C.P. Professor of Medicine in the University of London. The Abraham Flexner Lectures Series Number 3. Published for Vanderbilt University. Cloth Price \$2. Pp 135. Baltimore: Williams & Wilkins Company 1934.

It is difficult to write on the principles of therapeutics, and it may be impossible to write brilliantly on them or to avoid being platitudinous if one confines oneself to what is universally accepted. Dr. Fraser's book might serve as a gift to a medical student but it would not be of much profit to a mature physician.

Medicolegal

Pharmacy Practice Acts Hydrogen Peroxide a "Drug or Medicine"—Arthur, a manager of a pharmacy, was charged with violating section 13 of the California pharmacy practice act in that he permitted named persons, who were not registered pharmacists or assistant pharmacists, to sell peroxide of hydrogen. He was found guilty in the trial court and appealed to the appellate department, superior court, Los Angeles County, California.

Section 13 of the pharmacy practice act makes it unlawful for any *proprietor* of a pharmacy to permit the sale of drugs, medicines or poisons by any one except a registered pharmacist or assistant pharmacist. The defendant contended that since he was not a *proprietor* but a *'manager,'* his conviction was unwarranted. The superior court held, however, that a mere statement in the charge that the facts alleged constituted a violation of one section of the pharmacy practice act did not prevent the court from upholding the conviction if the acts charged were prohibited by any other section. Section 12 of the pharmacy practice act, observed the court, declares it to be unlawful for *any person* to permit the sale of drugs and medicines 'in his or her store or pharmacy,' except by a registered pharmacist or registered assistant pharmacist. The words "his or her" do not necessarily denote ownership. They may signify simple possession. The purpose of the pharmacy act is to prevent the sale of drugs and medicines by any person not a registered pharmacist or assistant pharmacist. To carry out this purpose a penalty is imposed both on the unregistered person who sells and on the person in authority who permits him to do so. To limit the latter provision to proprietors only would tend to defeat this purpose, for many stores are owned by corporations which are not subject to the imprisonment provided as a part of the penalty. Furthermore, any proprietor residing out of the state, whether individual or corporate, would be entirely beyond the reach of the statute. Such a defeat of the purpose of the act may be avoided by giving to the words "his or her store or pharmacy" a meaning signifying any store or pharmacy over which the person charged has such control and authority as to enable him or her to prevent violations of the act by other persons.

The defendant next argued that peroxide of hydrogen is not a drug or medicine within the meaning of the pharmacy practice act. We are satisfied said the court, that 'drug or medicine' are broad enough to include peroxide of hydrogen. It is a well known chemical substance, listed in the United States Pharmacopeia and described in all encyclopedias. Its character and common uses are well within the scope of judicial notice. The defendant apparently cited *State v. Hanchette*, 88 Kan. 864, 129 P. 1184 where it was held that peroxide of hydrogen is not a medicine and hence its sale by unregistered persons was not prohibited by the Kansas pharmacy practice act. But, said the superior court we are not disposed to follow this case in its apparent holding that the word "medicine" is limited to

substances which are generally and popularly known as such, to the exclusion of those so regarded only by the medical profession. This is altogether too narrow a meaning for the word. There may be some difficulty in applying the pharmacy practice act to substances which have both a medical and a nonmedical use, but in the case of peroxide of hydrogen we are aided by the provisions of section 16 of the act, which provides, by way of exception to the general provisions of the act, that permits may be issued for the sale by unregistered persons in the rural districts of "simple household remedies and drugs," among which is listed peroxide of hydrogen. Such an exception gives rise to a strong implication that what is excepted would otherwise have been within the purview of the act.

For the reasons stated above the judgment of conviction was affirmed—*People v. Arthur* (Calif.), 32 P. (2d) 1002.

Liability of County for Emergency Medical Aid Rendered to a Poor Person—A Nebraska statute imposes a duty on a county to furnish medical aid to certain classes of resident poor. Madison County, through its proper officials appointed a physician to furnish such aid. The appointment of this physician did not seem to have been generally known among the medical profession in the county. A certain person, entitled to medical relief from the county, became ill from a diseased appendix. Her attending physician called the appropriate county commissioner, who authorized the patient's removal to a hospital but refused to authorize the surgeon's bill. The commissioner however, did not ask that the patient be attended by the county physician or even refer to him. At the instance of the attending physician the plaintiff-physician, Sayre, performed an appendectomy and the patient recovered. The case apparently was one of great emergency and a delay in operating might have been fatal. The county paid the hospital bill but refused to pay the operating physician. He brought suit and the trial court gave judgment for the county. Sayre died but the action was revived in the name of his executrix, his widow, and she appealed to the Supreme Court of Nebraska.

The question presented by this case, said the Supreme Court, is whether a physician, not employed by the county, may recover from the county for services rendered a poor person in an emergency when the county has duly appointed a physician to care for the poor who was able, willing and ready to serve, but was not consulted. It was the duty of the county to furnish medical aid in this case, continued the court, but not necessarily to furnish the poor person's choice of medical aid. Statutes of the kind under consideration should be given a very liberal construction, and county officials should be generous in supplying the aid which the legislators intended for destitute persons. When, however, a county in Nebraska provides a physician to supply medical care to indigents, said the court, who is able and competent to give satisfactory service, and when that physician is ready and willing to render such service on call, then the duty of the county is fulfilled. Under such conditions, it is not permissible for the sick person to choose who shall render the service to him. The Supreme Court concluded, with one justice filing a dissenting opinion, that under the circumstances here involved the county was under no liability to pay for the services rendered by Sayre. If the county physician had refused or had been unable to attend or had been incompetent to take care of the case a different question might have been presented, observed the court.

The judgment of the trial court in favor of the county was affirmed—*Sayre v. Madison County* (Neb.), 254 N. W. 874.

Current Medical Literature

AMERICAN

The Association library lends periodicals to Fellows of the Association and to individual subscribers to THE JOURNAL in continental United States and Canada for a period of three days. Periodicals are available from 1925 to date. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 12 cents if two periodicals are requested). Periodicals published by the American Medical Association are not available for lending but may be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.

Chronic Congestive Splenomegaly and Banti's Disease

—On the basis of a study of forty-seven cases, Larrabee expresses the view that in the majority of patients presenting the clinical picture of Banti's disease (splenomegaly with fibrosis microcytic anemia with leukopenia and a late stage with hemorrhages and ascites) the condition is dependent on various intra-abdominal lesions obstructing the venous outflow of the spleen. By far the commonest of these is liver cirrhosis of various types. As Banti has limited the definition of the disease that bears his name in such a manner as to exclude these cases it is thought best to segregate them under a distinctive name. However, splenectomy is indicated just as in Banti's disease, regardless of the nature of the underlying lesion. The physician or surgeon confronted with an actual case need not trouble himself with theoretical questions as to the nature of Banti's disease. If he has a patient showing the Banti pre-operative picture if he has watched the patient long enough and studied him carefully enough to exclude leukemia, hemolytic jaundice polycythemia and certain other conditions, and if ordinary surgical considerations favor splenectomy, he need not hesitate to operate because he believes that the patient has alcoholic cirrhosis or some other equally definite cause of portal obstruction.

Distinction Between Splenic Anemia and Subleukemic Splenic Reticulo-Endotheliosis—Giffin and Watkins report two cases originally diagnosed as splenic anemia and subsequently classified as subleukemic splenic reticulo-endotheliosis. The first of these was seen in an early stage of the disease, the second was more advanced at the time of the first examination. The clinical and morphologic features that should have suggested an earlier diagnosis of splenic reticulosis are as follows: history of preceding episodes of infection, a short history of the development of splenomegaly slight purpuric manifestations with abnormalities of coagulation, leukopenia or normal leukocyte count with relative lymphocytosis and, in prolonged study of blood smears the presence of reticulo-

endothelial cells and the reticular type of monocyte. As the cases became more definitely leukemic, a higher percentage, between 20 and 30, of reticular cells could be found, even though leukocytosis was not present. The advanced stages in both cases were characterized by severe macrocytic anemia which did not respond to treatment. The infectious hyperplastic type of reticulo-endotheliosis, in which reticular cells may be found in the blood smears, may be distinguished from leukemic reticulo-endotheliosis by the presence of an increased percentage of polymorphonuclears, the absence of immature reticular monocytes and clinical manifestations of a predominating infectious process. Cases of subleukemic monocytic myelosis reveal the presence of stem cells of the myeloid series and the absence of typical reticular cells. In splenic anemia, there is usually no definite history of episodes of infection, a history of fever is uncommon and splenomegaly usually has been present for years. Purpuric features are occasionally present in cases of splenic anemia, but apparently they are not nearly so common as with reticulo-endotheliosis. In splenic anemia the test of liver function almost always gives evidence of at least a moderate, and sometimes an extreme, grade of retention of dye and gross gastro intestinal hemorrhage is more common. Leukopenia with lymphocytosis is not uncommon in splenic anemia but examination of blood smears, in addition to the absence of reticular cells usually reveals more poikilocytosis and less macrocytosis. Prolonged study of blood smears is essential to the demonstration of the presence or absence of reticular cells particularly in the early stages of splenic reticulosis.

Familial Hemorrhagic Condition Simulating Hemophilia and Hemorrhagic Purpura—Farber presents a study of a family of 113 members during five generations, of which twenty-five members suffer atypical pathologic hemorrhage, fourteen of whom are males. The family tree in regard to the males has a striking similarity to that of hemophilia, but the affliction is essentially purpuric in nature. The males have been more markedly involved four of their number having died directly from hemorrhage. The hemorrhagic incidents are variable but consist chiefly of prolonged frank bleeding from a cut or wound ecchymoses and epistaxis in the males and menorrhagia and ecchymoses in the females. The coagulation time of the blood is normal, bleeding time is intermittently prolonged, platelets are numerically adequate, and the clot retracts normally. Blood chemistry is normal. There seems to be no definite relation of the bleeding to season, diet, infection or occupation. Telangiectasia and splenomegaly are uniformly absent. Hypertension runs in the family, brain hemorrhages are frequent.

"The Bronchiectatic Septic Tank"—Bronchoscopic studies of the Jacksons indicate that the chief two primary causes of bronchiectasis are excessive viscosity of the primary pathologic bronchial secretions and the septic tank conditions they engender. The term 'bronchiectatic septic tank' means not only a receptacle for septic material but a container in which the material is changed in physical character and bacterial content by bacterial processes, chiefly saprophytic, in a way parallel to the changes that the sanitary engineer uses to change the physical character and bacterial content of household sewage. The difference is that the concrete walls of the sewage septic tank are not acted on by the changed character of the contents.

whereas the living walls of the bronchi are damaged by the inflammatory changes set up by the irritating character of the by-products of the septic tank processes. Putrefaction will ultimately thin the viscid secretions, so that they can be expelled by coughing but during the delay the septic tank processes have ruined the structural integrity of the walls. The chief means of preventing bronchiectasis is by forestalling the septic tank processes by bronchoscopic aspiration of the viscid pathologic bronchial secretions before they have time to rot. The primary pus in bronchiectasis is not coughed up, hence, when sputum is used bacterial studies are misleading and autogenous vaccines are inefficient. The important organisms are found only in the residual pus removed bronchoscopically from primary foci after the bronchiectatic septic tank has been emptied by bronchoscopic aspiration.

Carbon Dioxide Inhalation in Tuberculosis—Banyai found the administration of a mixture of 10 per cent carbon dioxide and 90 per cent oxygen by means of repeated inhalations to be a safe procedure in pulmonary tuberculosis. The most consistent benefits derived from this treatment were effortless expectoration, diminution of coughing and relief from dyspnea. Concomitant beneficial results were sustained rest for the diseased lungs during the absence of coughing, better and more relaxed sleep, improvement in the general well being, better appetite, and in some cases relief from laryngeal pain. The inhalation of carbon dioxide not only alleviates a distressing cough but also enables one to reduce the consumption of narcotics and expectorants in such cases. The treatment should be used only in selected cases, indicated in cases of strenuous exhaustive coughing without effective expectoration (1) if there is evidence of inflammatory exudation in the lungs, (2) when the cough is insufficient to evacuate sticky, thick sputum and thereby causes gagging, vomiting and incontinence, and (3) when sleep and rest of the patient are disturbed by coughing during the night. It is contraindicated in cases showing (1) hemorrhagic tendencies, because of a possible risk of inducing hemorrhage by increased respiratory expansion, (2) superficial, thin-walled cavities, because of the possibility of rupture and causing a pneumothorax, (3) marked emphysema, (4) widespread pulmonary fibrosis without atelectasis and without mucopurulent retention in the air passages, (5) acute plastic pleurisy and pleural effusion, (6) hypertension, (7) when the cause of dyspnea or coughing is outside the lungs, and (8) in extreme general debility.

Artificial Pneumothorax in Young Patients—Brock and Mullen studied a group of 267 white tuberculous patients and 100 Negro patients between the ages of 12 and 21 years hospitalized in the sanatorium during the five-year period beginning September 1928 and ending September 1933. A comparison is made of results obtained in the three methods of treatment: artificial pneumothorax, phrenicectomy and routine sanatorium care. The study was also made to determine what effect the following factors might have on ultimate results in the different treatment groups: (1) sex, (2) age of patient, (3) amount of disease at the time of admission, (4) unilateral or bilateral disease at the time of admission and (5) positive or negative sputum following the period of hospitalization. The results show that young women in their teens obtain just as good results when hospitalized and properly treated as do young men of the same age. The results of treatment in this age group are just as favorable as those in older patients. The amount of disease with which a patient is admitted to the sanatorium plays a much greater part in determining end results than it is generally supposed and this is particularly modified according to whether the disease is unilateral or bilateral at the time of admission. When the sputum remains positive following hospitalization, the end results are uniformly poor. A negative sputum following hospitalization and treatment points to success of the treatment and favorable end results in the great majority of cases. In comparing the white and Negro races as to end results, the principal differences, regardless of the method of treatment employed, are the relatively low number of arrested cases and the high number of deaths in the Negro. Artificial pneumothorax therapy in this age group is far superior to other methods. If the diagnosis is made early enough and particularly before the disease becomes bilateral the chances for favorable end results are good following immediate and successful collapse

of the lung by means of artificial pneumothorax. The authors feel that this also holds true but to a lesser degree for the Negro. His disease is more frequently exudative with involvement of the lymph nodes in the hilus, and when this is present they feel that the chances for spread to the contralateral lung by way of the lymph canals, even in the face of a good collapse, is a possibility not to be overlooked.

- Colloidal Thorium Dioxide.—Alexander and his associates state that the injection of colloidal thorium dioxide into the carotid artery allows visualization of the cerebral arteries. It has been shown by Kwan that the procedure described by Moniz and modified by Löhr and Jacoby is feasible. From the literature suboccipital or lumbar injection of colloidal thorium dioxide appears to have important possibilities in encephalography. Its ultimate effect on the body has not yet been determined. Injection of colloidal thorium dioxide into the brains of dogs shows that it acts there as a foreign substance. No definite evidence of a special physicochemical destructive action on axis cylinders or on myelin sheaths could be demonstrated histologically in examinations covering a period of two months following the injection. The colloidal thorium dioxide is transported from the parenchyma of the brain to adjacent blood vessels at a rather quick rate and is thus carried away. Microscopic examination after injection into the brain shows that 1. The extension of the lesion produced in the brain is largely dependent

on mechanical factors attending the injection 2 Free granules of colloidal thorium dioxide are present in the brain only on the first day The first granular cells that carry off the granules of colloidal thorium dioxide appear on the first day in the brain tissue, on the second day following the injection, the substance appears in the adventitia and endothelium of the adjacent blood vessels 3 Leukocytic emigration is present on the first day and disappears on the second Following injection into the ventricle the granules of colloidal thorium dioxide are taken off by proliferating ependymal cells which become rounded free, mobile granular cells (ependymogenous granular cells)

Myelotomy of the Commissure—Putnam believes that in cases of intractable pain in the arm or shoulder the suggestion has doubtless been made that artificial destruction of the pain fibers as they cross in the decussation about the central canal would be a rational procedure The author has carried out this procedure in three instances The first patient was a woman with carcinomatous metastases in both axillae, with extreme pain The cord was exposed from the fourth cervical to the third dorsal segment, and a needle was inserted between the posterior columns at intervals of a few millimeters up and down the exposed area and maneuvered in such a way as to pass through the commissure It was found possible to carry this procedure to a segment or two beyond the limits of the laminectomy The patient was not upset by the operation and was completely relieved from pain until death two months later The second patient was a man with pain from carcinomatous metastases, apparently from the lung which affected both sides of the neck as well as the axillae The pain was so severe that doses of one-fourth grain (0.016 Gm.) of morphine did not wholly relieve it A procedure similar to that used in the first case was carried out, except that a special instrument was used which appeared to give better results than the needle In this case the section of the commissure was carried up to the first cervical segment The patient was not completely relieved of pain in the upper cervical segments The pain was however, dull and burning instead of sharp and codeine instead of morphine produced sufficient relief In the third case the operation ended fatally, and it doubtless represents an error in judgment as well as an error in technic The patient was a cachectic old woman almost moribund from carcinomatous metastases to the shoulders and neck She died following an operation in which the commissure was divided through the entire cervical region and the first two dorsal segments

Graduated Jugular Compression in Lumbar Manometric Test for Spinal Subarachnoid Block—Grant and Cone suggest that the graduated measured jugular compression which can be obtained by applying a blood pressure cuff with its attached sphygmomanometer to the neck provides a method for determining spinal subarachnoid block that has many advantages It gives a measured, graduated jugular compression, which can be duplicated exactly in the same patient It makes possible a standard that can be used from patient to patient The results obtained by different operators are in much closer agreement and are therefore more dependable

Surgical and Radiation Treatment of Carcinoma of Breast—Schwyzer believes that surgery, even in well localized mammary carcinoma, should be radical obeying Halsted's teaching Only exceptionally and for serious reasons may one deviate somewhat from this principle The radio knife is of great advantage in sealing the wound rendering it less ready for implantation The danger of implanting liberated carcinoma

cells during the operation is to be kept in mind constantly In far advanced conditions the excision of foul smelling ulcers by cautery or otherwise, followed or not by Thiersch transplantation, may become desirable When unbearable pain persists in recurrence after operation and the arm is greatly swollen and useless the author has seen great relief in one case from an interscapular exarticulation of the arm, as advised by Carl Beck Preoperative irradiation confined to three days appears of great benefit As this involves no loss of valuable time, it should be more readily consented to by many surgeons who would object to a delay of eight weeks, as some modern radiologists demand for preoperative treatment Such loss of time and the mental strain on the patient with the operation constantly before him is not to be underrated When radium is used, 50 mg or more over a wooden block 3 cm thick is applied to different fields, to the amount of from 1,200 to 2,000 mg hours as the case may require This, with a day or two of rest before the operation does not disturb the patient Postoperative irradiation, moderate in dosage but continued over a long period in many cases if possible even over a very long period, seems to be of greatest value The dose of a single postoperative treatment should range between 60 and 80 roentgens after from two to four stronger initial doses of about 130 roentgens The first three doses are usually given at intervals of one week, then the next two or three doses at intervals of two weeks After this the patients receive one treatment a month for two years, then for the next two years, if there is no particular reason to give more, one every second month, and if the patients live and one can make them see the value of perseverance, they get three or four treatments during the fifth and sixth years After this, in cases in which a poor prognosis was made originally the author likes to give a treatment twice a year for several years more Castration, as advised by some earlier authors, has apparently no marked effect on the course of the disease Though he operates in practically every case that is not too unreasonably far advanced, he feels that irradiation will gradually come more into its rights and is at present a most important help to surgery, preoperatively and postoperatively

Blood Transfusion—Lundv prefers the indirect method of blood transfusion To the already established method he adds sodium citrate as an anticoagulant and administers the blood to the recipient slowly in order to avoid chills and other untoward results The rate of administration is about 15 cc per minute He calls attention to two measures that in his experience have facilitated blood transfusion The first is the grading of the donor's veins as poor, fair, good or excellent, so that in an emergency one may call for a donor with good or excellent veins The second is that, in any case in which it is expected that blood transfusion or intravenous infusion may be necessary any time in the near future the skin overlying the good veins in the ankles, arms and backs of the hands of the recipient is marked with a dye so that if the intravascular pressure becomes markedly reduced, and ordinarily the veins would be difficult to find, one may insert the needle through the mark on the skin and more easily accomplish whatever intravenous injection is necessary

Use of Stock Vaccines in Chronic Arthritis—Sherwood analyzes 674 cases of arthritis treated with stock vaccine, of which 68 per cent were found to be improved markedly or

free from symptoms and an additional 22 per cent showed some improvement. The location of the arthritis, the age and sex of the patient, the severity of the symptoms and the type of disease do not influence the results statistically. Cases having symptoms less than three months respond more favorably than those of longer duration. After a duration of three months the length of time the symptoms have been present does not greatly influence the results. The presence of complications distinctly lessens the chances for satisfactory results. Four vaccines have been used the best results being obtained with a dilute modified respiratory vaccine.

Age of Onset of Pulmonary Tuberculosis—During a period of eight years, Habbe examined about 5,000 adults, the males predominating over the females in the proportion of about four to one. The average age of the entire group was 35 years. There were sixty-four cases diagnosed as active pulmonary tuberculosis, of which there were seventeen cases of minimal involvement, twenty-six cases of moderately advanced disease and twenty-one cases of far advanced disease. Two of the entire series of patients (both men) had roentgenologically normal lungs at the age of 29 and 30 years, respectively, and became roentgenologically and clinically positive at the age of 32 and 31. The man whose lungs were negative at the age of 30 and positive (far advanced) at 31 in all probability contracted the disease from his active wife or child. From the best evidence available, the man who at the age of 29 was roentgen negative and moderately advanced at 32 was living in a family in which there was no active tuberculosis. So far as the author has studied the material, he has obtained no evidence to disprove the opinion of Brown and Sampson as to the relative rarity of chronic pulmonary tuberculosis developing in persons who have roentgenologically normal lungs at the age of 25 years or older. He states that the fact of regular pathologic onset of chronic pulmonary tuberculosis in early adult life once proved, would be an important one for clinicians and roentgenologists alike. It would serve to intensify the search among young adults for clinically latent lesions, it would aid in a more prompt differential roentgen diagnosis in many cases when previously taken normal roentgenograms were available for comparison and in complicated lesions, such as mixed silicosis and tuberculosis it would give a better understanding of the time of onset and development of the several lesions.

Generalized and Vertebral Forms of Myeloma.—Denker and Brock present four instances of myeloma with neurologic complications. The first is an example of the generalized form of the disease. The other three illustrate the vertebral type in which the myeloma is circumscribed to vertebral and extradural tissues at the time of the rapid development of signs of spinal cord compression. The upper thoracic cord is usually the part involved. The patient is generally in the fifth or sixth decade of life. Roentgenograms may show destruction of the diseased vertebra. Laminectomy reveals a reddish gray extradural growth, removal of which is followed by great, if temporary, improvement. High voltage roentgen therapy and the wearing of a back brace are advised after laminectomy. Myeloma may be regarded as a malignant tumor of the bone marrow arising either from a single cell type, the plasma cell or perhaps from a number of different bone marrow elements. Depending on the type of cell plasmacytomas, erythroblastomas, myelocytomas and lymphocytomas have been differentiated in the myeloma group (Ewing). There is still a great deal of difference of opinion concerning the pathogenesis of these growths. Most pathologists regard either the plasma cells or the myeloblasts of the bone marrow as the original cells of the growth. The disease is rare. The flat, short bones the rib, sternum, scapula, skull and vertebra are especially involved. Soft gray or reddish gray masses start in the marrow, grow outward and replace the cortex of the bones. Secondary growths may appear in the liver, spleen, kidney, lung and sex glands. Myeloma occurs in the later period of life. Pathologic fracture of a rib or vertebra is a frequent late occurrence, in no other type of bone tumor does pathologic fracture occur so frequently (62 per cent of all cases). No definitely curative form of treatment for generalized myeloma is known. Craver and MacComb report favorable results in five of a series of six cases by the use of Heublein's method of total body roentgen irradiation. The prognosis is grave. The average duration of life is two years, the longest duration of any proved case being five and one-half years. Once the tumor has appeared in many bones, the diagnosis is easily made. The age group (fifth and sixth decades), multiple involvement of the short flat bones of the trunk, pathologic fracture of a rib, Bence-Jones bodies in the urine, progressive anemia, nephrosis and cachexia make a highly characteristic clinical picture.

Inorganic Constituents of Cerebrospinal Fluid Versus Ventricular and Loculated Fluid.—McCance and Watchorn state that ultrafiltration will not explain the amounts of potassium and magnesium found in ventricular fluids. Such fluids in fact appear to contain slightly more magnesium and less potassium than lumbar fluid. As regards these two ions, therefore, ventricular fluid is even less like a serum ultrafiltrate or a pathologic transudate than is the spinal fluid. Judged by their magnesium and potassium contents, loculated fluids taken from below spinal tumors resemble ventricular fluids or spinal fluids and not serum ultrafiltrates. Such loculated fluids appear to contain more calcium than fluids from the ven

tricles, normal cerebrospinal fluid or serum ultrafiltrates, and this may be connected with their large protein contents

Relation Between Sugar and Urea Contents of Blood and Cerebrospinal Fluid—In an attempt to determine the relationship between the sugar and urea contents of the blood and cerebrospinal fluid, Cummings and Carmichael observed that the levels of sugar and urea in the lumbar fluid do not rise in association with a normal rise in the contents of these substances in the blood. Estimations of ventricular fluid sugar demonstrate that only in abnormal conditions is there any rise in the fluid sugar in association with a rise in the blood sugar. The observations are in favor of the choroid plexus taking an active part in the control of the level of sugar and urea in the cerebrospinal fluid.

*Some Observations on Hypochromic Anemia and Its Relation to Pregnancy D T Davies and Ursula Shelley —p 1094
Crural Monoplegia of Cortical Origin W R Russell —p 1099
Sclerosing Solutions for Varicose Veins J W Riddoch —p 1101

Hypochromic Anemia and Pregnancy—Davies and Shelley give an account of observations conducted on fifty-one apparently normal women who were followed carefully through their pregnancy and of twenty who were frankly anemic after their last confinement. The anemia was hypochromic in character and the response to iron therapy good. Of the fifty-one patients who were followed through their pregnancy and puerperium, six developed some degree of anemia. All were apparently healthy when they were first seen and the majority were young women bearing their first child. Of the forty-five women who passed through pregnancy without exhibiting any anemia a normal gastric secretion was found in all. As Castle and Strauss showed, there is quite a definite although temporary reduction in acidity, especially in the third trimester but this is replaced by a return to normal in the puerperium. While the patients demonstrated this change, none showed any permanent reduction. The reduction in acidity might be enough to result in a temporary state of achlorhydria, as in two of the cases but this appears to be uncommon. The patients examined and found to be anemic showed a high incidence of anacidity. This abnormality was present in twenty-three of the twenty-six anemic patients—achlorhydria in fifteen and hypochlorhydria in eight. The analyses from which these figures are calculated were done some months after pregnancy in twenty and in the puerperium in six when the gastric juice would be normally at its highest. Achlorhydria or hypochlorhydria in these cases must therefore indicate a permanent change in the gastric secretion. The authors believe that the anemia in these patients is due mainly to the long standing gastric deficiency. The gastric anacidity results in a poor absorption of iron and, when pregnancy calls for an extra amount of available iron the mother's hemoglobin manufacture fails and anemia develops. Second in importance to the gastric secretion is the diet. While the need of the pregnant woman for an abundance of essential

substances is fully recognized, it is possible that the increasing importance given to the treatment of the toxemias of pregnancy and their early recognition has resulted in too great a readiness to advise restrictions in diet. The liberal use of iron will prevent the development of this anemia. It would not be impossible to forestall its appearance. A course of iron during pregnancy would ensure a good supply for the fetus without depleting the maternal stores. The testing of gastric function in pregnancy when anemia is present is of more than academic interest, and the presence of a permanent achlorhydria would be a sufficient explanation for the anemia, as well as being an assurance of the benefit of iron therapy.

*Blood Manganese in Some Nervous Disorders C I. Urechia G Pamfil and Mme Retezeanu —p 330

Blood Manganese in Nervous Disorders—Urechia and his collaborators used the colorimetric method in measuring the amount of manganese in the blood. It consists in the transformation of the manganese compound into the manganate ion. The total blood, erythrocytes or serums are weighed accurately, and 10 cc of nitric acid and 5 cc of hydrogen dioxide are added to destroy the organic substances. The mixture is evaporated in a water bath in a Jena glass to from 60 to 100 cc. during two or three hours. The reaction is ready when the mixture becomes perfectly clear and shows a yellowish coloration. The clear liquid thus obtained is evaporated to dryness in a porcelain crucible. The residue is heated over a low flame and finally over a stronger flame to destroy the organic substances and carbon. The dry residue is then mixed in a porcelain crucible with 0.5 Gm of potassium nitrate or potassium chlorate and 100 Gm of anhydride sodium carbonate. This is heated to complete fusion, so that a homogeneous mass is obtained. The oxidizing mixture transforms the manganese compound into manganate ion, which takes a green color. Similar steps are taken with titrated solutions of manganese salts containing 0.0001, 0.00005 and 0.00001 Gm of manganese per cubic centimeter. The color of the final products should be compared with the unknown for titration. In this manner the authors measured the blood serum manganese of thirty-nine patients affected by different nervous disorders. The values obtained varied between 0.00001 and 0.00003 per cent. Similar comparative tests were made on the erythrocytes of fourteen of these patients, in whom in general lower values were obtained. In general, therefore there is a smaller quantity of manganese in the cells than in the serum and it seems advisable to examine the serum or the whole blood. Their results did not allow conclusions to be drawn regarding the different nervous disorders.

Synthesis of Paired Menthylglycuronic Acid in Various Disturbances of Liver B A Nasarjan —p 1090
Congenital Torticollis C Martin-du Pan —p 1091

Pathogenesis of Thrombosis—Fomio and Vannotti believe that an impairment of the venous endothelium is the primary factor in the pathogenesis of thrombosis. Such an impairment may be produced by endogenous and exogenous factors. The first group includes all factors that cause a disturbance in the metabolism between blood and endothelium particularly changes in the blood such as postoperative increase in the viscosity of the blood, acceleration of the sedimentation speed of the erythrocytes, changes in the protein colloids of the blood, disturbances in the acid-base equilibrium, hypnosis and increased instability of the plasma. Toxins and infectious processes likewise may cause impairment of portions of the endothelium. The exogenous factors are those which damaging the vascular wall, finally impair also the endothelium. In this connection the authors mention infectious processes of the vascular wall or its sur-

roundings, which finally penetrate to the intima and produce an impairment of the endothelium (phlebotic processes caused by infection, syphilis, tuberculosis and so on), also traumas, burns, freezing and electrical influences. They describe experiments in which they induced exogenous impairment of the endothelium by electrical coagulation with a microcautery. Following this they studied the vessel under the capillaroscope and observed the gradual formation of a thrombus. They show diagrams of the process. Compression of the vessel leading to retardation of the blood stream was found to accelerate thrombus formation, but this was the case only in the presence of endothelial impairment.

Immunization by Inhalation—Silberschmidt has shown that the repeated inhalation of diphtheria toxin or of tetanus toxin produces temporary immunity in susceptible animals. He describes experiments concerning anaphylaxis following inhalation. He found that guinea-pigs which had inhaled serum developed typical anaphylactic manifestations following the intravenous injection of the same serum. In another series of experiments the action of inhaled toxins was studied. It was found that guinea-pigs die quickly following the inhalation of pure diphtheria toxin while diluted toxin causes death less rapidly. Mice and rats tolerated the toxin. Inhalation of tetanus toxin proved fatal to the three types of animals but mice and rats survived longest. Inhalation of toxin proved harmless in animals that had received a prophylactic injection of the specific antitoxin. The author studied what effect the inhalation of a 2 per cent solution of antimony and potassium tartrate would have on rats and mice that had been infected with pathogenic trypanosomes. The animals reacted differently. In some the inhalation caused the complete disappearance of the trypanosomes, while in others the parasites caused death. Some animals that became free from parasites died with the signs of antimony poisoning. Nevertheless the experiments demonstrate that trypanosomiasis may be therapeutically influenced by way of the respiratory tract.

Experimental Production of Dynamic Hydronephrosis—Ragnotti performed the denervation of the ureters in dogs, by chemical and mechanical means, for the purpose of investigating whether the so called dynamic hydronephrosis may be originated in the denervation of the ureters by itself or whether anatomic alterations of the structure also play a part and, if this is the case, to what extent they are responsible in producing the condition. The author determined the relationship of the structural changes of the ureter after denervation and its functions (studied in vitro by a method used to stimulate peristaltic activity) on the one hand and the alteration of the kidney on the other. He concludes that chemical denervation sympathectomy provoked by the application of isophenol (a cresol-phenol derivative) to the internal coats of the ureter causes transient alterations of the peristaltic movements of the ureter without interfering with the pendular movements of the ureter as well as ureteral and renal structural lesions which follow a regressive evolution as the nervous system of the ureter regenerates and do not end in the production of a hydronephrotic ureter. The mechanical denervation produced by decortication of the ureter results in the formation of connective tissue in the internal ureteral coats which interferes with the motor functions of the ureter and with the elasticity and distensibility of the ureteral walls. The condition progresses to the development of more or less grave hydronephrotic functional disturbances and anatomic alterations, both of which become more serious as the ureteral lesions grow worse and a vicious circle becomes established. Disturbances of the ureteral innervation cannot by themselves produce hydronephrosis. Therefore the pathogenesis of experimental dynamic hydronephrosis is mechanocodynamic.

Id. IV. Potassium and Calcium Blood Content in Hemolytic Shock A. Mineev—p. 250

Cardiac and Vascular Alterations in Blood Transfusion—From experimental studies, Petroff and his co-workers conclude that intravenous introduction in animals of the animal's own hemolyzed blood or of heterogenous blood produces alterations which are analogous to a hemolytic shock with a predominance of alterations on the part of the heart and the vascular system. The pathogenesis of these alterations is not explained. The authors have undertaken experiments to elucidate the problem. They have demonstrated by registering the heart volume and determining the arterial and the venous blood pressures that the fall in cardiac activity in hemolytic shock is a secondary phenomenon resulting from a diminished venous return to the heart. Experiments with determinations of blood pressure in the pulmonary arteries and veins have demonstrated likewise that cardiac failure in hemolytic shock is a secondary phenomenon and that the lumen of finer vessels of the pulmonary circulation becomes narrowed. These alterations do not play an important part in the hemodynamic disturbances. Experiments with volume determinations of kidneys, spleen, hind legs and brain indicate that the introduction of hemolyzed or foreign blood causes a marked narrowing in the lumen of the renal and splenic blood vessels. The circulation in the brain and in the hind legs was only slightly affected. In a fourth series of experiments, circulatory disturbances were studied in the vessels of the intestine and of the hind legs as well as the alterations in the capillary system in the presence of an intact nervous system. These experiments demonstrated that the main alterations in the circulatory system in hemolytic shock proceed from the alterations in the walls of the arteries and the veins. These changes consist of dilatation and even of paralysis of the capillaries and narrowing of the lumen of the arteries and the veins of the systemic circulation. The alterations in the functional activity of the heart and circulation are secondary to the alterations in the peripheral circulation. The disturbances were more marked when hemolyzed erythrocytes were introduced than after the introduction of blood plasma.

Pathogenesis of Vascular Changes in Hemolytic Shock—Wesselkin and his co-workers state that typical hemolytic shock may be induced in the dog by transfusing it with its own hemolyzed blood with whole blood or with hemolyzed human erythrocytes. The symptoms are particularly acute when human erythrocytes are used. The authors have been able to substantiate the basic experiments of Hesse and Filatov as to the spasm of the renal arteries constituting a characteristic symptom of the acute stage of shock. The diminution of the volume of the kidney develops at the same time independently of the fall in blood pressure but becomes more pronounced with a simultaneous fall in the latter. The duration of the renal spasm varied in their experiments from twenty seconds to thirty minutes. Repeated transfusions of the dog's own hemolyzed blood, of heterogenous whole blood or of erythrocytes had a tendency to diminish the severity of shock or to abolish it altogether. The kidney responded no longer with a spasm but, to the contrary, with dilatation. Decerebration, sectioning of the spinal cord immediately below the medulla oblongata, sectioning of the two splanchnic nerves below the diaphragm removal of the celiac ganglion and of the two sympathetic trunks in the abdominal cavity, as well as total denervation of the kidneys failed to prevent the renal spasm in hemolytic shock. The partly denervated kidney reacted weakly with a spasm to hemolytic shock. When the renal vessels were directly transfused with hemolyzed blood, a rapid and pronounced contraction took place in them with a diminution of the renal volume as demonstrated by an oncograph. The authors conclude that the renal spasm in hemolytic shock

is of peripheral origin and that the nervous system plays an unimportant secondary part in its development. The acute picture of hemolytic shock resembles closely that of histamine shock. It is possible that histamine-like substances play an important part in the pathogenesis of the acute hemolytic shock.

Renal Activity on Introduction of Autohemolyzed Blood.—Iljin experimented with transfusions of human blood in dogs. The fatal single dose varied in amount between 15 and 20 cc. of blood per kilogram of the animal's weight. The introduction of the same amount and of larger amounts of dog's own hemolyzed blood failed to kill the animal. A single transfusion with human blood resulted in a marked diminution of the urinary output and a rise of the residual nitrogen in the blood, which reached its peak in from twenty-four to forty-eight hours. The rise in nitrogen content of the blood is caused by the disturbance of the renal function, but the latter is not the only factor in accumulation of nitrogenous products of albuminous decomposition in the blood. Repeated transfusions of human blood in amounts of 7 cc. per kilogram weight of the animal caused a greater rise of residual nitrogen than a single larger dose. Renal activity in that instance was less disturbed. Disturbance of the renal activity cannot alone be held responsible for the vascular phenomena of shock following the introduction of heterogenous blood. The introduction of the dog's own hemolyzed blood results in milder disturbance of renal activity than the introduction of heterogenous blood.

Diagnosis of Backache in Young People.—In evaluating the causes of backaches in young persons, van Schrick calls attention to a postural defect, which he ascribes to a disturbance in the equilibrium between gravity and muscular action, a condition usually accompanied by prolapse of the shoulders, protruding abdomen concave back and fallen arches. The usual complaints are that the child gets easily tired and is absent-minded and weak. The physician commits a grave error if he diagnoses such cases simply as manifestations of growth for the postural defect may exert a detrimental influence on the general condition. A reform of the school routine would be helpful in counteracting and preventing this disorder. The author shows how the contracted postural defect may be differentiated from the kyphosis of adolescents. In the latter condition a flattening of the sides of the thorax becomes manifest, so that the oval shape of the thorax disappears and it assumes the shape of a trapezium. Roentgenoscopy reveals disturbances of the marginal bands of the vertebral bodies. The author considers the disturbances in the calcium-phosphorus quotient which were observed in these cases an indication that the kyphosis of adolescents is really a late form of rickets and he found that antirachitic treatment exerted a favorable influence on this condition. He considers a three months rest cure in a plaster-of-paris cast with gradually increasing muscular exercise the most essential measure in this disorder. He advises against creeping exercises. Dull drawing pains in the back of children with a rather lax posture may be caused by a disturbance in the growth of the cartilages. However, this disorder is rather rare. Percussion pains are manifold and can be elicited in various conditions. The percussion pain that is limited to a small area is generally indicative of a tuberculous process. It is wrong to assume that the formation of a gibbus is necessary before tuberculous spondylitis can be diagnosed. He maintains that one or even several vertebrae may be involved in a tuberculous process without the presence of a gibbus. When the origin of a restricted percussion pain is doubtful a specialist should be consulted, because the treatment may require years if the development of a gibbus is awaited. In some instances

the percussion pain may be caused by osteomyelitis. He stresses the value of roentgenoscopy particularly for the detection of vertebral fractures. If backaches appear during the third decade of life, a spondylitis deformans may be the cause. This disorder often becomes manifest by an increasing rigidity of the muscles which results in limitation of thoracic breathing. A wearing down in the vertebral articulations is another cause of backaches. Loosening of the sacro-iliac connections leads to backaches that are extremely refractory to treatment. He discusses sacralization and evaluates changes in the musculature that cause backaches. Sites of predilection of these disorders are between the scapulae, in the lumbar region and at the point of insertion of the gluteal muscles. He calls attention to abnormalities of the pelvis and emphasizes the necessity of a thorough examination of patients with backaches.

Chemical Methods for Diagnosis of Pregnancy.—Menken states that Visscher and Bowman perfected two chemical methods for the diagnosis of pregnancy. The first one is done in the following manner: To 1 cc. of urine is added one drop of a 0.5 per cent solution of hydrogen dioxide. Then five drops of a 1 per cent aqueous solution of phenylhydrazine hydrochloride is added and five drops of a 5 per cent aqueous solution of methyl cyanide, and finally five drops of concentrated hydrochloric acid. This mixture is placed for twenty-five minutes in a boiling water bath. The reaction is positive if a russet color and a flocculent precipitate appear. A straw color and a powdery precipitate or the complete absence of a precipitate indicate a negative reaction. The second method is supposedly more sensitive but also more complicated. To 1 cc. of urine one drop of a 0.5 per cent solution of hydrogen dioxide is added and this is allowed to stand for three minutes. After that five drops of 1 per cent solution of phenylhydrazine hydrochloride is added and then five drops of a 5 per cent aqueous solution of potassium ferricyanide. This mixture is allowed to stand for ten minutes at room temperature and then put into a boiling water bath for fifteen minutes. After that one drop of concentrated hydrochloric acid is added and this is followed by an excess of sodium hydroxide. Then titration is done with diluted hydrochloric acid until the color changes from orange to green and finally to blue. It was found that to produce the final color required much less diluted hydrochloric acid in pregnancy urine than in urine from women who were not pregnant. The author reviews the results obtained by Visscher and Bowman, who obtained 93 per cent correct results, and then describes his own experiences with the first method. He emphasizes that the reagents must be fresh. Contrary to the experience of Visscher and Bowman, his positive reactions generally showed a dustlike and occasionally a somewhat more disperse precipitate. Only once did he obtain a clearly flocculent precipitate. He says that the color was generally dark in positive reactions and light in negative reactions. He thinks that this simple chemical test will be welcomed by the practitioner because it is rapid and dispenses with the use of animals.

*Juxta Articular Nodules. M. Wolf—p. 1420

Behavior of Leukocytes and of Other Blood Cells in Case of Mikulicz Disease Following Short Wave Treatment. L. H. Stiebeck—p. 1422

Varicose Syndrome of Rectum.—Blond shows that the customary terms of nodules of the anus, fissures of the anus, periproctitis, erythema of the anus or pruritus of the anus are only morphologic terms for a disease entity, the varicose syndrome of the rectum. In case of stasis in the region of the portal vein, conditions of stasis develop at its origin and it is surely not accidental that in women the first hepatic colic develops following their first pregnancy or that varicose veins or hemorrhoids develop at this time, for the hemorrhoidal plexus belongs to the region of origin of the portal vein. Suppurations in the region of the source of the portal vein, which include periproctitic abscesses, fistulas and fissures, are the port of entry for bacteria into the liver. French authors have called

attention to the high incidence of hepatitis in the anamnesis of diseases of the biliary passages and the author decided to examine cholecystectomized patients from this point of view. Studies in 100 cases revealed the high incidence of existent or of a history of fistulas and fissures in patients who had undergone cholecystectomy. Pruritus ani is often complicated by pruritus of the vulva or of the scrotum and the author points out that this may be explained on the basis of the anatomic connection between the hemorrhoidal plexus and the pudendal plexus. Stasis in the hemorrhoidal plexus and reflux from the system of the portal vein into the region of origin of the inferior vena cava by way of the pudendal, vaginal and uterine plexus may lead to a number of disturbances in the small pelvis the genesis of which is not entirely clear as yet. It is possible that certain diseases of the female pelvis and of the male genitalia are causally connected and there is a connection between high hemorrhoids and chronic constipation.

Juxta-Articular Nodules—Wolf reports the history of a man aged 34 who developed juxta articular nodules first on the right hand then on the left and later on both elbow joints. The predominating localization on the hands is rather unusual but can be explained by the patient's occupation. The disorder is more frequent in tropical regions than in the temperate zone and the majority of investigators are of the opinion that it is caused by frambesia. In many cases observed in the temperate zone a connection with syphilis has been assumed. Spirochetes have been demonstrated repeatedly in the nodules of patients in the tropics but it could not be determined whether they were of the pallida or the pertenuis type. In the cases occurring in the temperate zone the demonstration of spirochetes has not succeeded as yet. One investigator assumed the existence of a fibrotropic strain of spirochetes. In many instances the past history of the patients reveals syphilis in which the anti-syphilitic treatment has been inadequate or entirely neglected. The author's patient likewise had had syphilis but had also lived in a tropical region where frambesia is endemic without developing signs of that disease. The fact that the nodules disappeared following treatment with bismuth compounds and arsenamine seems to be a further indication of their syphilitic origin and the histologic structure of the nodules seems to point in the same direction.

Scientific Theory and Clinical Problems of Renal Calculi O. Schwarz —p. 163

*Treatment of Schistosomiasis Haematobium M. Loewenack.—p. 202

Treatment of Schistosomiasis Haematobium—Loewenack states that patients with schistosomiasis haematobium complain of cystitis that proves refractory to treatment with teas and with urinary antiseptics. Microscopic examination of the urinary sediment clarifies the diagnosis. The author emphasizes that at this point it is inadvisable to force a cystoscopic examination, because it causes hemorrhage and exacerbates the symptoms. Irrigations and instillations are likewise useless and annoying at this period, but the painful vesical tenesmus usually disappears after several injections of an isotonic solution of an antimony compound. This preparation is injected in increasing doses on several successive days, and on about the sixth day it is possible to resort to cystoscopy. If polyp-like granulomas are found, it is generally possible to remove these soft masses and the sandlike deposits mucus and pus by suction with the Morgenstern instrument. If a hemorrhage should result, it may be arrested by a diathermic sound introduced through the irrigation canal. The injections of the antimony compound are continued. The mixed infection is counteracted by irrigation, and in approximately three weeks the patient is free from symptoms. In a patient observed by the author, a control examination after four weeks revealed that eosinophilia had persisted and that ova were still present in the material withdrawn by suction although the patient was free from subjective symptoms. A new series of injections with the antimony compound was instituted and the eosinophilia gradually disappeared. The antimony compound was well tolerated. The author emphasizes that the disappearance of the eosinophilia is the only reliable sign of cure.

*Albuminuria and Histogenesis of Nephrosis J. Bing —p. 508

*Studies on Significance of Macrophages in Malignant Tumors. W. Münch —p. 514

Mechanism of Albuminuria—Bing's observations support the modern conception that the mechanism of albuminuria depends on a filtration of plasma proteins through degenerated glomeruli. Accordingly he considers the histogenesis of nephrosis best explained by invasion and storage, during the work of concentration in the tubuli, of plasma proteins (and plasma lipoids) which are filtrated through degenerated glomeruli in the glomerulus filtrate.

Macrophages in Malignant Tumors—Following his experimentation, Münch presents the following working hypothesis. In the growth of malignant tumors there is caused in the surrounding tissue a mobilization of mesenchymal cells originating partly from the tissue itself, partly from the blood, which appear in large numbers as large mononuclear ameboid cells. These macrophages are functionally connected with the reticulo-endothelial system and with regard to the tumor tissue exercise a function which consists partly in taking up various substances, including degeneration products from the tumor cells and partly in contributing to the formation or further production of the substance that is important for the growth of the tumor cells. In epithelial malignant tumors the function of the macrophages is of secondary importance and the nature of the tumor is primarily dependent on the epithelial elements. In mesodermal malignant tumors the macrophages seem to constitute a functionally important link between the tumor cells and the normal cells and are the main place of formation of the substances on which the malignancy of the tumors depends.

*Contribution to Clinic of Intestinal Disorders II Significance of Catalase (and Triboulet) Reaction in Diagnosis and Prognosis. S. Kemp and T. T. Andersen —p. 1349

Significance of Catalase in Intestinal Disorders—Following investigations on the catalase relations in the feces in 1716 cases of intestinal disorders, Kemp and Andersen conclude that practically only the catalase values which show a marked increase are of diagnostic and prognostic significance. The main diagnostic importance of the catalase reaction in intestinal disorders is in directing attention to the possible presence of a deep-seated organic disturbance especially when the reaction is pronounced and confirmed on repeated examinations. Continued normal catalase values testify against but do not exclude a grave intestinal disorder, particularly when there is a possibility of latent tuberculosis. The quantitative catalase determination supplements the results of rectoscopy, examination for occult blood and roentgen examination, and in many intestinal disturbances, including grave disorders without ulcerations, neoforations or stenosis it is the best objective criterion of the more or less grave nature of the disturbance and of the results of treatment. In ulcerous intestinal disorders the catalase reaction gives a more reliable impression of the entire course than the more accidental occult hemorrhage when positive and negative results vary. The marked catalase reaction, which except in grave manifest hemorrhage is probably never due to gastric ulcer is also useful in distinguishing between gastric and duodenal ulcer. The catalase reaction is preeminently indicated in (1) all chronic diarrheas, (2) obstinate colitis with constipation, especially when there is proctitis, (3) suspected cancer or tuberculosis of the intestine and (4) acute specific intestinal infections, particularly in convalescence, for control of the results of treatment, and (5) as a supplementary examination in chronic and acute amebic dysentery. The Triboulet reaction in its marked positive form is almost synonymous with grave, usually purulent intestinal disorders, but its infrequent occurrence (except possibly in intestinal tuberculosis) considerably lessens its value in practice. The qualitative catalase reaction is of doubtful value.

EARLY CUTANEOUS CARCINOMA

RICHARD L. SUTTON JR., MD
KANSAS CITY, MO

In practice, one sees not infrequently circumscribed epithelial new growths that in theory are difficult to classify. Some of them develop into carcinoma. I have interested myself in an attempt to determine which lesions have this potentiality, for it should be possible to identify carcinoma in its exceedingly early phases.

It is plain that a new growth which has appeared where previously there was no growth must, while now obvious, have been at one time borderline, before that invisible, and before that nonexistent. The argument bears no controversy that a lesion having arisen *de novo* must have had a beginning and must have progressively evolved.

The problem arises, At what point is a carcinoma not a carcinoma? At what point does a process appearing *de novo* attain the status of cancerousness?

I am of the decided opinion that, at least in many instances, it is correct to think that cancer is cancer from the start. The concept of carcinoma developing from a 'degenerated verruca,' or from a 'precancerous keratosis,' is to my mind vague, indecisive, unclear and not representative of the truth.

It is common experience that abnormal aggregates of cells do *de novo* become clinically apparent, do progress over periods of weeks, months or years, do increase volumetrically, in two dimensions of surface and one of thickness, and do ulcerate and enlarge and cause by their presence and activity of growth deleterious effects in their host.

A man, aged 60, had a raised rounded, crusted lesion 1 cm. in diameter and from 3 to 4 mm thick on the skin of the left preauricular region. One year previously there was no lesion of any kind to the best of his knowledge. A small 'freckle' appeared, scaled off and seemed to be gone later recurred and attracted his attention six months before. It had enlarged rapidly in the past month crusting and bleeding when the crust was removed. Excised with the actual cautery this tumor was composed of a mass of irregular, multinuclear and polymorphous epithelial cells that underwent atypical keratinization, and it was diagnosed squamous cell carcinoma.

I quote this one instance in substantiation of the thesis that cancerous lesions come into existence on sites previously normal—a fact of common experience.

The next problem is to establish cases of indubitable carcinoma to examine new growths of a less advanced

stage, and to show that they are of the same nature but simply less advanced and that they differ not qualitatively but quantitatively. I agree with Broders¹ that "the entity called carcinoma, regardless of etiology, is a primary disease of epithelial cells, and all other phases and sequelae, though of great importance, are in reality of secondary nature." The clinical entity called carcinoma, I consider fundamentally a colony or culture of abnormal epithelial cells growing parasitically on a host. I therefore make the assumption that a carcinoma is a carcinoma independently of its size. This is a reasonable biologic assumption, analogously, a solitary fertilized ovum is as truly an individual living entity as is the adult into which it grows.

The difficulty in studying what might be called embryo specimens of carcinoma lies in the fact that one never excises a portion of a lesion, allows a part to incubate on the host, and removes additional bits from time to time until a full blown, uncontrollable cancer has evolved from the remainder. Such an experiment is easily conceived, and it would yield specimens showing indubitable steps in progress. But, if it should be done, while it might indicate the steps of continuous evolution of a carcinoma, yet objection would be based on the effect of traumatism and inflammation on a lesion that might otherwise not have taken such a course.

The material from which one is forced to derive one's concepts, therefore, is not so fortunately consecutive as is ordinary embryologic material. Lesions that one arranges as consecutive stages come from different individuals at different times, and a series composed of them suffers from the objection that it is not an unbroken series. This is unfortunate, but there is no other way. If one can show that cases of circumscribed epithelial tumors, arising in different individuals, nevertheless possess characteristics that vary only in quantity and hence presumably only in duration, rate of progression or stage of progress, one will have satisfied oneself that they represent the same thing.

It is my custom, in treating a patient with what I believe to be an early carcinomatous lesion, to remove the entirety of it as a cylindric disk of dermis and epidermis, with a margin of normal tissue as narrow as I believe to be safe, by means of the actual cautery. The tissue removed is sectioned and the prepared slide examined to determine that the excision has gone beyond the margin of the atypical growth laterally as well as in depth. In no single case in my experience wherein the microscopic evidence has been clear that the tumor has been removed in toto has there been a recurrence.

Read before the Section on Dermatology and Syphilology at the Eighty-Fifth Annual Session of the American Medical Association, Cleveland, June 14, 1934.

1 Broders, A. C. Carcinoma in Situ Contrasted with Benign Penetrating Epithelium. J. A. M. A. 99: 1670 (Nov. 12) 1932.

The material for this study has been furnished by specimens removed as described. On examining them microscopically, I have seen many intergradations between definite, advanced carcinoma and very early processes that appear to me to be simply less advanced lesions of identical basic nature.

It is to be kept in mind that in every case I describe, I am limited by the human impossibility of knowing what the lesion would have developed into had it been left alone. As Heilmann says "No one on earth is clairvoyant enough to select a given pigmented macule and point with certainty to its epitheliomatous future."

While the concept of a disease process should include its progression in time the microscopic examination of a particular lesion is temporarily stationary.

Histologic pictures depict only a state, they show only coexistent features, not a chronologic sequence."² I am endeavoring histologically to show that the structure of certain early and small lesions is such that it is reasonable to presume that if they were merely allowed to

The appearance in vertical section was as of tubules cut longitudinally. About 2 mm from the surface all the cylinders were solid, and they became convoluted with lateral buds, so that vertical sections did not follow the axis but cut some buds tangentially so that they appeared as horny pearls, and others so that they appeared as circular and oval islands. Many such islands contained concentric laminae of keratinized and desquamated cells. Some contained loosened cells that were almost homogeneous and eosinophilic. The external layer of cells of both the cylinders and the islands were more than normally variable in size; their outline was less sharply distinct, their nuclei varied in size, shape and uniformity of staining and in keratinization they tended to retain their nuclei and cell outline, which varied in size and was frequently huge as compared with the normally keratinized epithelial cell of the nearby corneum. Around some of the cylinders and outbuddings that appeared like islands the peripheral layer was seen to proliferate into the loose cellular stroma in strands of thickness of only one or two cells.

The downward extent of the tumor mass into the loose, soft tissue of the lip was fairly sharply demarcated from the muscle fibers against which it had pushed. The border zone was narrow. While there was no capsule, the round cell infiltration dense about the epithelial buds left off sharply and was limited to the region only of epithelial growth.

The sections showed that normal tissue surrounded the tumor laterally and beneath.

This case is plainly carcinoma. Had the growth not been interrupted the downgrowths would have continued. The abnormal mass would have enlarged, ulceration and sloughing would have occurred and further increment in tumor quantity with attendant necrosis, infection and absorption would have led to the patient's death.

CASE 2 (figs 2 and 3) —A man, aged 59, was first aware of a 'fever blister,' which appeared on the lower lip about six months previously. This did not heal, and he continued to smoke with the pipe stem against the sore. The lesion had steadily and rather rapidly increased in diameter and thickness. It had been a crusting lesion from the start, but now the crust was more extensive; the lesion bled when the crust was forcibly removed and it was tender and painful on pressure. The new growth was somewhat raised fairly sharply circumscribed, firm to the touch, and set in the superficial portion of the lip like a whitish, lenticular disk with a granular, oozing surface. It was 11 mm across and practically circular, it felt about 3 mm thick in the central part, the edges being thin and continuous with the mucosa. It had received no treatment but had been injured slightly several times by the pipe stem. No regional lymphatics were palpable.

The tumor was excised with a margin of normal tissue by means of the pointed cautery and sectioned vertically through the middle. Microscopically, an epithelial proliferation was found embedded in the lip tissue to a depth of 2.8 mm, in a stroma of densely infiltrated round cells. The downgrowths were in such narrow cylinders and strands that the central portions of them had not keratinized, and only in some deeper aggregates had degeneration of centrally located epithelial cells occurred. There was I presume, sufficient surface for nutrient exchange so that within only the largest epithelial aggregates had keratinization occurred. Outbudding was so pronounced that a large proportion of the section showed epithelium in apparent islands. The surface from which the cylinders took their departure was covered by layers of epithelium of only one or two cells and the stroma was not only densely infiltrated with round cells but contained many dilated capillaries engorged with blood, and many red blood cells were seen outside capillary walls. Many of the infiltrating leukocytes were polymorphonuclear and the crust, composed of irregular and parakeratotic epithelial debris, was also purulent. In the larger epithelial aggregates within the tumor the cells were larger than normal, stained paler and were not regularly arranged. The peripheral layer was composed of lavender-staining cells that were variable in size, shape, chromatin content, and uniformity of staining. Round cells were seen interspersed between

Fig. 1 (case 1) —Branched and budding tubular masses of neoplastic epithelium invade the lip to a depth of 4 mm. The stroma is composed of densely infiltrated round cells. The epithelial cells are large, keratinize abnormally, and possess irregular nuclei. This is plainly carcinoma.

continue proliferating they would attain the structure, dimensions and characteristics of what is generally considered carcinoma.

CASE 1 (fig 1) —A man, aged 77, had a scalp spot on the lower lip to the left of the midline for perhaps eight years, though he had stopped smoking a pipe twelve years before. The patch had slowly and continuously thickened especially in the past year and its rate of growth seemed progressively increasing. It was now a rough crusted plaque set in the lip tissue raised only slightly about 1.5 cm across, oozing and bleeding when the crust was removed. It was sharply circumscribed and felt hard and firm; it seemed about 0.5 cm thick. It was asymptomatic except for tenderness on pressure. It had received no treatment or traumatism. The regional lymphatics were not palpably enlarged.

The tumor was excised with a pointed cautery and the whole lump was sectioned vertically through its middle. Sections stained with hematoxylin and eosin showed an epithelial tumor embedded in the lip tissue to a depth of 4 mm in a stroma of densely infiltrated round cells. The tumor epithelium took its origin from the surface layer and grew down in cylindric masses. Near the surface some of the cylinders had a lumen that was partly filled with keratinized and desquamated cells.

the epithelial ones, and in the central portions of the largest aggregates irregularly cornified, eosinophilic degeneration products were found, constituting horny pearls and peculiar in being in many instances hollow and filled with leukocytes, and so constituting minute abscesses. The zone of epithelial growth limited the round cell infiltration, which, beneath the tumor, as in the preceding cases, was sharply demarcated from the

Fig 2 (case 2) —The epithelial downgrowths reach a depth of 2.8 mm. in this circumscribed crusted lesion of the lip. The zone of demarcation from deeper tissues is well defined. The stroma is like that of case 1 and case 3.

deeper lip tissue. At the margins of the tumor the downgrowths were shallow, at the central region they reached a depth of almost 3 mm, so that the lesion in the gross was lenticular.

The sections showed that the line of excision was well beyond tumor growth laterally and in depth.

I do not hesitate to call this carcinoma. It is clearly an infiltrative epithelial proliferation with microscopic and clinical evidence of active and atypical growth. In its probable further progression, had it not been interrupted it is rationally presumed that it would have infiltrated deeper and more widely, ulcerated and sloughed and produced a clinical picture completely reconcilable in all its attributes with the concept of carcinoma.

CASE 3 (figs 4 and 5) —A man of about 65 had had a circumscribed thin, asymptomatic scaly patch on the right side of the lower lip for about two years which appeared insidiously and without attracting attention. It had slowly thickened and was now a firm, whitish sharply margined, scaling and crusting plaque oval, about 5 by 6 mm in surface and it felt about 1 mm thick. The central part was slightly thicker than the edge. It was not painful and had received no treatment. It was removed with the pointed cautery with a margin of normal tissue and sectioned.

The sections showed epithelial tumor embedded in lip tissue to a depth of 1.1 mm. The epithelial downgrowths were roughly cylindric or ovoid bulging with rounded ends. They were not all aimed perpendicular to the surface so that some were cut axially and others at an angle. They filled the large proportion of the tumor area of the section. What stroma was present was composed of densely infiltrated round cells and capillaries engorged with blood. The epithelial downgrowths tended to branch and bulge. Their peripheral layer was not so regular as was the normal basal layer and in proliferation formed little buds about the blunt ends of the downgrowths. In places these tended to loosen and extended out into the stroma. Within the

aggregates of epithelium the cells were paler and larger than normal and tended in the larger aggregates to keratinize and form whorls. Such whorls in some places had become clear and distinct horny pearls, only 0.5 mm from the surface. The zone of adjunction of tumor and deeper tissue was densely infiltrated with round cells, which were limited to the region of epithelial growth and demarcated it sharply from the sub-jacent tissue.

If this new growth had not been interrupted, it is reasonable to presume that the downgrowths would have extended. As their constituent cells multiplied in numbers, more outbuddings would have been produced, more horny pearls would have developed, and deeper invasion would have ensued. As the mass increased and the depth of invasion progressed, a picture resembling that of case 2 might reasonably be imagined to have evolved. Therefore while this is an early and small lesion, it is my conviction that it is cancer.

CASE 4 (fig 6) —A woman, aged 70 had a small, scaling dome-shaped flattened, circular reddish yellow papule 6 mm in diameter located on the left cheek. It had been present not more than six months. It scaled slightly and itched a little at times. It was increasing in size steadily she said. It felt about 1 mm thick. It was removed with the pointed cautery and sectioned.

Microscopically, it was seen that the epithelium of 6 mm. of the surface was much thicker than normal in actual measurement it reached a depth of 1 mm. Rounded papillary epithelial downgrowths extended into a stroma composed of densely infiltrated round cells and many capillaries. This infiltration was sharply limited to the zone of epithelial abnormality and it sharply demarcated this from the deeper connective tissue. The whole process was limited to the superficial half of the dermis, and sebaceous and sudoriferous gland structures were found beneath the new growth at a depth of 1.6 mm from the surface. The downgrowing processes were somewhat looser in structure than those of case 3 and took more the form of strands than fat cylinders. The epithelial cells were separated a little more from one another but the peripheral layer was equally irregular. The cells were also larger than those of the normal,

Fig 3 (case 2) —The neoplastic cylinders are narrower and more branching. Their central keratinization in whorls produces horny pearls and outbuddings are so pronounced that much of the epithelium appears as islands.

and the interior cells of the aggregates had likewise the tendency to undergo keratinization and to group themselves in whorls.

It is reasonable to believe that if this process had not been interrupted the downgrowths would have proliferated and extended deeper. As the aggregates increased in size, their central tendency to keratinize

and to form whorls would have manifested itself in the production of full-blown horny pearls. The branching outgrowths from the cylindric processes would have become more complex in configuration, so that sections would show apparent islands. The massive structure thus evolved would satisfy every criterion of true carcinoma.

Fig. 4 (case 3) — Sections of this scaly plaque show broad downgrowths that branch a little. The depth of extent is quite sharply delineated and the total thickness of tumor tissue is 1.1 mm.

This lesion might be called a senile keratosis. As Hookey⁴ states, "the microscopic picture of keratoma senilis suggests the possibility of further evolutionary changes of malignant character." Eller and Ryan⁵ observe that "when a senile keratosis becomes verrucous, it is a carcinoma." It is my opinion that case 4 is already carcinoma.

Malignancy, I believe, is a property of the tumor cell. The tumor mass, or clinical carcinoma, has no properties excepting those of its constituent elements. As Fraser⁶ writes, "From the pathologic point of view, the cells in Bowen's lesion have already undergone the changes of malignant neoplasia, and for this reason the lesion should be classified as intra-epidermal carcinoma, not as precancerous." I believe that the cells of the lesions I have described are also already neoplastic.

A capacity for unrestrained growth and invasion can only be interpreted from, not observed in, any histologic preparation. It cannot by any human means be predicated as more than a presumption about any lesion that one sees, not imagines.

The lesions that I have presented have originated in the squamous layer of the epidermis. They are structures which, one may reasonably believe, would have evolved into gross carcinoma if not interrupted.

One must consider the present interpretation of precancerous lesions. The idea of a "precancerosis," a term first used by Dubreuilh in his thesis at the third

International Dermatologic Congress at London in 1896, according to Bloch,³ is commonly used to imply, among other lesions, some such lesions as I have described, particularly in cases 3 and 4. I believe that the differences between these cases are basically insignificant and I have described them in accordance with this belief.

Definitions of "precanceroses" such as I am dealing with are vague. Cramer⁷ says "Precancerous is used in strictest sense as designating a condition which will develop into a malignant condition with a high degree of certainty." Sulzberger and Satenstein⁸ define it thus: "The term precancerosis is a term which must be kept to designate conditions which, while not yet cancer, will, if untreated, practically invariably become cancer." Bloch's³ careful review gives this definition: "We call precancerous those pathologic changes in tissue which, without being cancer, show the tendency sooner or later to develop into actual cancer." He calls this a "clinical-statistical" definition and bases it on two points: (1) the determination with mathematical certainty of the probability that a lesion will become cancer, and (2) the reaching of agreement on the percentage probability at which one is satisfied that a certain type of lesion is precancerous. That is, if 50 per cent of such lesions do become cancer, all such lesions may rightfully be considered precancerous. The concept remains unclear. Heimann² says "The term 'precancerous dermatosis' has that alluring quality which captivates the imagination and courts acceptance until analysis reveals that it is inappropriate. At what point does precancerous lose its prefix? Is the problem one of medicine or etymology?"

Fig. 5 (case 3) — Higher magnification shows the irregularity of the neoplastic cells, the tendency to keratinize in whorls, a horny pearl so formed and a stroma quantitatively scant but qualitatively the same as in the preceding cases.

I have asked these questions, too. Bloch's definition is untenable. It makes a basic error in attempting to apply mathematics where mathematics is inapplicable. It is humanly impossible to determine the probability

of a lesion's becoming cancer, for five reasons
 1 Either a lesion does become cancer, or it does not, so that a lesion is not statistically eligible
 2 If one examines the structure of a lesion, it is bottled in formaldehyde and has no biologic future
 3 If one has not determined the structure of the lesion and it becomes cancer, it is impossible to know what its structure was
 4 Before any lesion has become cancer predictions about it are based on subjective, not objective, data, being based on presumption and not on perception
 5 After a lesion has become cancer, it is impossible to say when it was not cancer
 If a lesion is interrupted, it has a structure either compatible with the possibility of being early cancer or not compatible in which case it must be thought of as being either probably early cancer or probably not early cancer

Bloch continues "Of certain precanceroses, such as keratosis senilis, precancerous stage of xeroderma pigmentosa, of Bowen's and Paget, it may be said that in principle they always turn into cancer. Actually however, the changes may occur so slowly that often the patient does not live the required number of years" Of this, I argue that, if the host is interrupted (e.g., by old age and death) and if the observer has the temerity to state that the lesion would have become cancer had the host lasted longer, the lesion must fall into the category of those which do become cancer and hence are cancer

It is hopeless to attempt to decide at what percentage probability of becoming cancer a lesion may be called precancerous, because it is impossible to arrive at knowledge of this probability. Bloch admits that "reliable figures do not exist." I believe that such figures cannot exist. One must distinguish the connotations of "lesion" in the generic sense such as senile keratoses in general, and "lesion" in the specific sense of this particular tumor on this particular patient. In the error of indiscrimination between these two meanings, the one collective and the other particular, lies the confusion of all statistical effort. Specific lesions not yet examined histologically are not yet diagnosed. Hence lesions collectively are not susceptible of a statistical assay with respect to their individual futures.

The concept that precancer is that which is not cancer but does become cancer is a concept not susceptible of scientific demonstration and outside the possibility of human proof.

One might define precanceroses as those lesions which may or may not be early cancer and cannot be decided on. Then one would be using the term "precancerosis" to designate a state of doubt as to whether the lesion is or is not early cancer. This is not a desirable usage. Bloch states that the concept of precancerosis is of practical importance because "the knowledge of precancerosis gives us the only means of practicing effective prophylaxis of cancer." This statement is erroneous, for, plainly, the effective prophylaxis of cancer depends on recognition of early and curable actual cancerous lesions, and on the knowledge of what may be early cancer. Nothing is gained by calling early cancer any other name, and any doubtful lesion ought as appropriately to be destroyed as a lesion regarding which there is no doubt.

One might define precanceroses as those lesions which are becoming cancer. But in such a definition the dividing line between precancer and cancer is implicitly admitted to be impossible. And precancer automatically becomes early carcinoma.

With the last possible meaning of "precancerosis" as, etymologically, rightly "that which precedes the earliest cancerous lesion," the precancer must be invisible. Should still earlier lesions come to light precancer must still precede them.

Hence I am led to conclude that precancerosis has not been defined and cannot be defined, it is an idea.

Fig 6 (case 4).—This dome-shaped dyskeratotic papule shows on section primary abnormality in the epithelium. The tendency to grow downward is evident. The cells tend to group and keratinize in whorls. The sizes of the cells and their nuclei are irregular. The cellular infiltrate is the same as that in the preceding cases. The total thickness of this very early carcinoma is 1 mm.

not an observable reality, and as a concept deserves recognition only as a confusing makeshift.

This removes the difficulty from the field of theory into that of practice. It may be hard to decide whether a lesion is or is not cancer. While the diagnosis may be, the lesion is not, on the fence.

The criteria of early carcinoma are difficult to arrive at. Broders⁹ diagnoses his "carcinoma in situ" by the "altered cellular characteristics, in contradistinction to the cellular situation." Bloch states "We know of no single macroscopical-clinical, or microscopical-histological change which is generally typical or pathognomonic." He lists

- (a) Proliferation and hypertrophy of epidermis of irregular type.
- (b) Unrest and irregularity of the whole epidermal structure.
- (c) Increase of mitoses, irregular and pathologic mitotic figures.
- (d) Polymorphism of cells particularly of nuclei (giant, double and multiple, micronuclei, clumping of nuclei, etc).
- (e) Dyskeratotic manifestations.

These features may be summarized as evidences of cellular malignancy or neoplastic alteration. Hanse-
mann's¹⁰ concept of "anaplasia," used to explain the origin of cancer cells, is not sufficiently specific in meaning. I am in agreement with the hypothesis of Whitman¹⁰ that, in view of the atypical mitoses, multipolar divisions, hyperchromatic and hypochromatic

⁹ Hanse-
mann, David. *Virchows Arch f path Anat* 119: 229 (Feb 4) 1890.

¹⁰ Whitman, R. C. *Somatic Mutations as a Factor in the Production of Cancer*. *J Cancer Research* 4: 181 (April) 1919.

nuclei, asymmetric mitoses and changes in the number of chromosomes, the cancer cell is 'a new kind of cell, strictly and literally a mutated cell.' The earliest clinical cancerous lesion is then the smallest visible colony of progeny of a mutant somatic cell. The earliest theoretical cancerous lesion is the first mutant cell which, altered by mutation retains its visibility, reproductive capacity and potentiality of being the ancestor of a parasitic colony, and loses its responsiveness to the host's control of its growth. One can imagine that a mutant may not be viable and so never produce a clinical lesion, the mutant may be partially controlled and so produce benign lesions, or there may occur many mutations within one atypical cell colony, resulting in a tumor with several kinds of cells in it, such as basosquamous lesions. With this hypothesis a precancerosis might be understood to be a lesion in which neoplastic mutation is likely to occur. In the lesions I have described however it is my belief that the mutation has already occurred and that the status of cancerousness has already been attained.

CHARACTERISTICS OF EARLIEST RECOGNIZABLE SKIN CARCINOMA

On the basis of the foregoing considerations, I describe earliest recognizable skin carcinoma from three standpoints: the clinical, the microscopic and the theoretical. Clinically they are circumscribed epithelial lesions that have arisen *de novo* generally brownish, rough, scaly or verrucous in character, asymptomatic or slightly pruriginous, occurring by predilection on surfaces exposed to sunlight or irradiation, especially in persons with sun-sensitive skins. Microscopically, they manifest epithelial irregularity, acanthosis and dyskeratosis with changes in cell type of the order of abnormal mitoses and atypical morphology and with evidence of the probability of proliferative extension into a dermis that is characteristically infiltrated to a greater or less degree with round cells in the immediate region of epithelial abnormality. Theoretically, they are interpreted as colonies of progeny of mutant epidermal cells with retained capacity for proliferation and lost responsiveness to growth control on the part of the host.

Such a description is independent of the size of the lesion in accordance with the theory that one cell can constitute a cancer. It is independent of rate of growth of the lesion for the progression may be so slow as never to interfere with the well being of the host. It stresses the concept that carcinoma in the gross is purely a manifestation *en masse* of epithelium growing abnormally. It conceives relative malignancy as dependent on balance between proliferative capacity of tumor cells and resistance of the host. It explains multiplicity of cell type in one tumor on the basis of mutation following on mutation. It enlarges the concept of skin carcinoma and it offers a reasonable and unified conceptual design for the interpretation of neoplastic processes. It is eminently practical, for it encourages suspicion of minute lesions which might grow into gross carcinomas.

The therapeutic correlate is that if a lesion may cause serious trouble later now is the time for its destruction.

CONCLUSIONS

- 1 (a) Many skin cancers begin as *de novo* lesions.
- (b) The earliest visible lesion in these cases is a circumscribed, scaly epithelial new growth.

- 2 (a) The structure of many minute, scaly, epithelial new growths is such that it is reasonable to presume that if not interrupted, they would become obvious carcinomas.

- (b) It is reasonable to believe that such lesions are in fact early carcinomas.

- (c) If a lesion has a structure not compatible with a likelihood of its being early carcinoma, it might be called precancerous. But it would be impossible to predict that such a lesion might develop a structure if uninterrupted, such that it would be properly called carcinoma.

- 3 (a) It is impossible to determine at what point in its natural history a cancerous lesion was not cancerous.

- (b) It is reasonable to believe that cancer is cancer from the start.

- 4 The concept of precancerosis is indecisive and undefinable. It groups unrelated conditions which may or may not be early cancer. Its acceptance entails an insoluble problem of a dividing line between cancer and not-cancer, as well as an insoluble problem of statistical assay of lesions that are strictly individual.

- 5 (a) A lesion may be cancerous independently of its size and rate of growth.

- (b) Cancer is primarily an epithelial disease.

- (c) A cancer consists of mutated somatic cells.

- (d) The earliest visible manifestations are circumscribed, dyskeratotic lesions which microscopically are composed of polymorphous epithelial cells that proliferate, keratinize and undergo mitosis in an abnormal manner.

- (e) Malignancy depends on a balance between the proliferative capacities of its cells and the control or resistance of the host.

- (f) One tumor may contain several kinds of cells as a result of mutation following on mutation.

- 6 Early cancerous lesions are readily destroyed and cured. In suspecting all early lesions and destroying them, one would prevent the development of all late lesions such as might become incurable.

801 Lathrop Building

ABSTRACT OF DISCUSSION

DR. E. W. NETHERTON, Cleveland. To obtain the best results the correct diagnosis must be established at the earliest possible stage. Early diagnosis followed by complete surgical removal is still one of the best methods of treating squamous cell carcinoma. This type of management makes possible a thorough histologic study of each lesion which is essential if the benign and doubtful lesions are to be separated from those of early carcinoma. A statistical study of a large series of early cases which had been treated in this fashion with observation of the patients over a period of years would be of considerable value. What is especially needed is some criterion by which the benign and early malignant epithelial new growths can be differentiated by their gross morphologic characteristics. In many instances the microscopic examination does not give conclusive results. The greatest difficulty is encountered in the borderline cases and it is not unusual for equally clever pathologists to differ in their interpretation of the clinical and microscopic observations. The term precancerous has been used for years to designate the malignant potentiality of lesions such as leukoplakia, senile keratosis and xeroderma pigmentosum. Dr. Sutton has given many good reasons why the concept of precancerosis is indecisive and undefinable. It is impossible to determine the future of any benign epithelial growth nevertheless the conditions that have been designated as precancerous will in a high proportion of instances become malignant but since nothing is known concerning the specific etiology of can-

cers there is no way of telling which apparently benign lesions will become malignant. It is difficult for me to agree that a senile keratosis, a leukoplakia, or a melanotic mole that has been present for years and has become malignant, was in reality cancerous from the start. Paget's disease of the breast and Bowen's keratosis by pathologic evidence have been shown to begin as cancerous lesions, but this is not the case with other types of so-called precancerous dermatoses. Precancerous is a poor term, but usage has established it firmly in medical nomenclature. If in its strictest meaning 'precancerous' denotes that the lesion will invariably become malignant if its course is uninterrupted, it should be discarded, for, as Dr Sutton has stated, such a statement concerning any particular lesion cannot be verified. However, if precancerous means that a certain lesion is potentially malignant and that it is probable that it will become malignant I can see no objection to its use. It would be better to designate such lesions as potentially malignant. What is most important is that all early and potentially malignant lesions be recognized and removed or destroyed.

DR. HAROLD N. COLE, Cleveland. I have had the opportunity of looking over Dr. Sutton's histologic material. I know that he has painstakingly made serial sections on dozens of new growths attempting to come to some conclusion on the argument advanced by Broders of a carcinoma *de novo* of its being a carcinoma from the beginning. It is only by such studies that some conclusion can really be reached as to when a malignant condition starts or whether it does actually start from the beginning or whether some of the lesions are going to remain precancerous and continue the same.

DR. JEFFREY MICHAEL, Houston, Texas. I have tried to study as many biopsies as possible of these early lesions. It all comes down to a question of a pathologic concept and a definition. If a cancer is defined as a tumor that must have invasive qualities, one cannot call these early lesions malignant. But if Broders' contention is accepted that there is such a condition as an epithelioma *in situ* which can be differentiated by certain cytologic changes in the cells, one should accept these changes as cancer from the beginning. I think that the old pathologic concept of invasive qualities being absolutely essential to a diagnosis of malignancy is being broken down in two directions in the first in the conception of Jadassohn and Borst that there is an intra epidermal epithelioma and in the second place in the conception of Broders that there is such a thing as epithelioma *in situ*.

DR. RICHARD L. SUTTON JR., Kansas City, Mo. The arguments that I wished to present are not nearly complete. The idea that cancer in order to be called such must be an invasive lesion is to my mind not essential. A cancer is a structure composed of a number of cells of originally epithelial origin which represent a true mutation from an originally presumably normal somatic cell. That is the idea of Whitman, whom I have quoted. Cancer cells in general have been shown to vary in their cytology, in their number of chromosomes and so the alterations that take place within them are those of true mutation in the biologic sense. They have fewer or more chromosomes than normal and their progeny have atypical divisions. In my opinion, one cell that retained its capacity to proliferate but lost its capacity for being controlled by the host on which it was proliferating would constitute a cancer. Certainly one melanocarcinoma cell in a capillary in the liver would constitute a cancer in the sense that such a metastasis produces a separate colony of living cells capable of proliferating there and doing further damage. One sees these peculiar cells *in situ*. All one has to do is to examine lesions in order to find them. Broders has pointed them out in numerous instances, and in looking over many sections I have seen them too. I imagine that they represent somatic mutations and so colonies of mutant cells that have the capacity for invasion. The word malignancy has so many different meanings that it is hard to know just how to apply it to this concept of cancer. One can't tell whether the cells of a lesion are proliferating or whether they are invading; one can't see them acting because as soon as one looks at them microscopically one has killed them; they are in formaldehyde. So it is a mixture of clinical and microscopic evidence from which one must derive one's concepts.

BORDERLINE BREAST TUMORS

BIOPSY AND POSTBIOPSY TREATMENT

JOSEPH COLT BLOODGOOD, M.D.

BALTIMORE

There is still a good deal of difference of opinion among those best informed as to the type and method of biopsy and as to prebiopsy and postbiopsy irradiation in breast tumors.

I have been observing the results in all breast tumors in which the tumor has been explored first. The object of this exploration was to determine its pathologic nature. Up to 1915 in the Halsted Clinic at Johns Hopkins, the naked-eye diagnosis had been depended on. In my own experience since 1915 I have used naked-eye diagnosis in every case, but, in addition an immediate frozen section for microscopic study was resorted to in the operating room, and the operation or treatment that followed rested largely on the diagnosis made on this immediate frozen section.

Great changes have been observed and recorded by me since the first exploration that I witnessed on a borderline breast tumor more than forty-two years ago.

These changes have been forced on the operator and his surgical pathologist by the decreasing preoperative incidence of malignant tumors in the clinic and the increasing occurrence of benign and borderline tumors. In the last five years, borderline tumors in which it is difficult to determine whether they are malignant or benign have greatly increased in numbers.

In the first fifteen or twenty years of the Halsted Clinic more than 98 per cent of the women complaining of breast lesions had definite lumps in the breast and were subjected to immediate operation. In fully 80 per cent of these cases the tumor proved to be malignant. In my own clinic today only 15 per cent instead of 98 per cent, are subjected to operation, and the incidence of cancer in the total number is less than 10 per cent, and the incidence of malignant tumors in those subjected to operation is less than one half. The pathologic type of the distinctly palpable breast tumor subjected to exploration which has shown the greatest increase in the past three years is the borderline breast tumor, which I¹ described in detail in a paper published in 1932. There are fifty-eight illustrations in that paper, and since the date of its publication two and one-half years ago, the number of new cases has been equivalent to what I had previously observed in twenty years.

METHOD OF BIOPSY IN DOUBTFUL CASES

The method of biopsy is employed when the palpable mass is small enough to be excised with a good margin of uninvolved breast tissue and the wound closed without producing loss of symmetry in the breast. In these cases the gross and microscopic appearance of the tumor is not seen until the tumor is bisected when held in the hollow of the left hand of the operator, studied with the naked eye and an immediate frozen section made and examined. If the operator and his pathologist are confident that the tumor is distinctly benign the wound in the breast is closed and no post-operative irradiation is employed. When the operator and his pathologist are confident, from the gross

Read before the Section on Surgery, General and Abdominal at the Eighty-Fifth Annual Session of the American Medical Association, Cleveland, June 14, 1934.

¹ Bloodgood, J. C. *Am J Cancer* 16: 103 (Jan.) 1932.

appearance and the frozen section, that the tumor is distinctly malignant, an alcohol sponge or a gauze sponge saturated with a 50 per cent solution of zinc chloride (and squeezed dry) is placed in the wound, the skin sutured over it and the complete operation for cancer performed at once.

These two procedures for tumors of the breast, when there is no doubt about their pathologic nature, have

Fig 1—Appearance of patient about one year after the excision of a clinically benign but microscopically doubtful or borderline breast tumor removed during the early months of pregnancy. The circle in ink on the forearm represents the palpable subcutaneous tumor that was removed June 13 1932 under procaine hydrochloride and proved to be a benign nerve sheath tumor. This patient was free from a recurrence of either tumor in July 1934 two years and some months after the operation on the breast.

been accepted by the majority of operators, pathologists and radiotherapists. I am beginning to accumulate evidence which clearly indicates that there is no danger in closing the wound, without either the alcohol or the zinc chloride sponge after the removal of the malignant tumor, and in subjecting the patients to postbiopsy irradiation. I am beginning to accumulate evidence that, when the malignant tumor is smaller than a twenty-five cent piece (24 mm) and has been present one month or less, its local excision and postoperative irradiation may offer as many chances of a permanent cure as the radical operation. In a number of such cases of which I have records, operation has been done in this way (in other clinics and in a few in my own clinic) when the patients refused the complete operation.

The third type of breast tumor is that in which the operator and his pathologist are in doubt as to a malignant condition. This is the true borderline tumor. From my study of borderline tumors since 1892 I have found, with the rarest exceptions, that they are benign. If the complete operation is performed immediately or later, the axillary glands show no metastasis. Practically all patients with such borderline tumors have been followed from five to forty-two years. In not a single case up to the time of death, or at the present time if the patient is living, has there been any sign of malig-

nancy in the scar or of internal metastasis. The percentage of malignant involvement of the other breast has been identical with that in an equal number of benign adenomas of the breast at the same age and followed through the same periods of time.

There seems to be largely an agreement among the greatest authorities as to this method of biopsy when exploration must be done to determine the pathologic type of the tumor and when the tumor is sufficiently small to allow its excision through uninvolved breast tissue and the closure of the defect in the breast without producing loss of symmetry.

To repeat, the majority of expert authorities urgently advise the immediate complete operation should the operator and his pathologist decide that the lesion is distinctly malignant. Of course, they all agree to the restricted removal of the tumor of the breast only when it is agreed that it is benign.

There is a great difference of opinion as to the method of procedure in the borderline tumor. I am advising the treatment of the borderline tumor on the operating table as one treats the benign tumor, but after the operation I advise irradiation of the breast and axilla while sections are being submitted to two or more widely experienced surgical pathologists.

In many instances this biopsy can be done under local anesthesia. If the operator plans to perform the complete operation, should the tumor prove to be malignant, he should work in the operating room of a hospital with full preparation for the complete operation. When the operator who has had experiences similar to mine and feels justified in closing the wound no matter what the nature of the tumor may be, and give irradiation first even if the complete operation is to be done later, it is not essential that the patient be prepared for the complete operation.

There is no question that the education of women has increased the number coming to the clinic with benign conditions of the breast for which operation is not indicated. Also there is no doubt that transillumination in a dark room, as first advocated by Dr. Max Cutler of Chicago, has done more than any other

new procedure for the distinct recognition of a benign blue-domed cyst larger than a twenty-five cent piece. In my clinic we no longer subject to operation distinctly palpable tumors larger than a twenty-five cent piece unless they transilluminate dark.

There is a fourth group of tumors that are increasing in numbers with the exploration and complete excision of clinically benign tumors of the breast. These

Fig 2—Appearance of a bisected tumor from the breast of the patient shown in figure 1.

tumors are solid and have the distinct gross and microscopic appearance not only of a malignant growth but of a grade IV acute carcinoma, that is, the type of tumor which, if neglected by the host, develops ultimately into cancer *en cuirasse*. My entire experience teaches me that in every stage of its development this grade IV acute carcinoma is best not subjected to operation. So far they have never been cured but the

Fig 3—Section showing nonencapsulated tumor removed during early months of pregnancy from patient shown in figure 1. This section was taken from the center of the tumor showing stroma of the old adenoma and definite gravidity hypertrophy of the parenchyma.

duration of life is often prolonged and the patient made distinctly more comfortable by proper irradiation without the complete operation, even when the tumor is observed in an inoperable stage or is recognized with the microscope in a frozen section at the exploratory biopsy for an apparently benign tumor of the breast.

One has to bear in mind that the actual change in the relative number of malignant breast tumors which are still clinically benign and must be explored is toward an increase. I am convinced of this because it has been shown in excised breast lumps sent to me for examination. The women of this country are showing the results of the educational efforts of the American Society for the Control of Cancer, the medical societies, and individuals in the medical profession. When 80 per cent of distinct breast lumps are cancer and more than 95 per cent of these are evidently so clinically exploration for a malignant tumor is the exception rather than the rule. In many hospitals today there is an increasing number of breast tumors explored in the operating room, an increasing number submitted to frozen section in the operating room, and an increasing number in which the pathologist is in doubt as to the diagnosis. The pathologist must be able to advise this group what to do in case of doubt. In fact, in the most experienced clinics in the world today the number of borderline tumors found at exploratory biopsy is on the increase. Every surgeon and his pathologist know what to do when the breast tumor is distinctly benign and they still know what to do if they wish to follow the major opinion when the breast lump is distinctly malignant. Very quickly the educated community will

force on the operating surgeon and his pathologist an increasing number of borderline tumors.

In my opinion, the proper procedure is the complete excision of the palpable lump, by cutting through uninvolved breast tissue, by closing the wound and by giving postoperative irradiation to the breast and axilla.

There is a difference of opinion among radiotherapists as to the time that should elapse before the closed wound in the breast is irradiated. There is no doubt that if begun at once the wound may break down, and if this wound becomes infected, it interferes with the value of irradiation. I am advising the irradiation at once when the frozen section favors an ultimate diagnosis of malignancy and have advised delay when the section favors a benign condition. By great care of the wound, should it break down, infection can be avoided. In view of the fact that there is such a difference in ability among even well trained surgical pathologists to recognize the malignant tumors of the breast in their earliest stages, I am inclined to the view that it may be safer to give irradiation over the axilla at once, protecting the breast wound and giving irradiation over the breast and its wound within a week or ten days. In three cases subjected to immediate irradiation the wound broke down but did not become

Fig 4—Periphery of tumor shown in figure 3. A typical hypertrophy of the parenchyma.

infected and healed perfectly by granulation. In many instances the wound did not break down. So far I have observed no bad results from irradiation.

SECOND TYPE OF EXPLORATORY BIOPSY OF BREAST TUMORS

Halsted, beginning in 1889, in his clinic at Johns Hopkins when he explored a breast tumor cut directly down into it with the knife, and if its naked-eye appearance suggested to him a malignant growth, he

cauterized the cut tissue with phenol (carbolic acid) followed by alcohol, closed the wound, changed instruments and towels and performed the complete operation for cancer. Such explorations were of rare occurrence and the patients were most carefully followed. We could never find evidence that this explora-

Fig 5—Areas of tumor shown in figure 3 which many pathologists diagnosed malignant many benign

tion followed at once by the complete operation decreased the chances of a permanent cure. When the glands were not involved 70 per cent of the patients were living at the end of five years whether there had been an exploration or not. In the majority of breast tumors explored, the glands were not involved. When the glands were involved, the five-year cures did not seem to be affected by an exploratory incision followed at once by the complete operation.

Halsted was so confident of his naked-eye diagnosis that he was very late in adopting frozen sections. I have only one positive case in which Halsted failed to recognize a malignant condition by the naked-eye appearance of a breast tumor and restricted his operation to the removal of the tumor only. The tumor was a smooth-walled and thick-walled cyst containing blood. There was no papilloma. Cancer was not recognized in the wall until permanent sections were studied within one week. The complete operation was then performed and the removed glands in the axilla and above the clavicle showed metastasis. The patient died of internal metastasis. In a letter to Dr. Welch, written some two years before Dr. Halsted died, he expressed great satisfaction over his ability to recognize with the naked eye the correct pathologic condition of tissue exposed at operation.

Another evidence of this extraordinary ability of Dr. Halsted is the borderline tumors he explored up to 1915. In not a single instance did he look on this non-encapsulated tumor as malignant. After cutting into it he excised it as he would an encapsulated benign tumor or a blue-domed cyst. He closed the wound without performing the complete operation. The tumors were then sent to the laboratory. In the early years they were diagnosed adenocarcinoma by Dr. Welch. After

1892 they were diagnosed by myself, usually in consultation with Dr. Welch. Dr. Halsted accepted the microscopic report of malignancy and performed the complete operation. As I have already said, the axillary glands were never involved and these patients lived for years and before or at death showed no signs of cancer. In 1915 I submitted the section from these borderline tumors to a large number of the best trained surgical pathologists in New York, Philadelphia and Detroit. The written diagnosis of the majority was malignancy or suspicion of malignancy. There was never a unanimous vote in favor of malignancy. There was always a minority in favor of a benign condition. Many of these cases have already been reported.¹ These identical sections have been again referred to a group of pathologists and surgical pathologists who attended the microscopic diagnostic demonstrations in the Surgical Pathological Laboratory of the Johns Hopkins Hospital in the last four years. In every instance there is still a difference of opinion, but the larger number vote benign while in 1915 the majority voted malignant. Sections from malignant tumors of the breast submitted to these groups are always diagnosed without exception malignant. Therefore, when two or more pathologists of average training and ability differ as to the malignancy of a breast tumor, the chances are that it is benign and will be cured without a more extensive measure than the removal of the tumor only.

These borderline tumors are on the increase. The present paper is designed to call attention to the fact that when the tumors are small enough the method first followed by Halsted should be changed to the complete removal by cutting through uninvolved breast tissue. But when they are too large for this method they may

Fig 6—Section of the normal breast in pregnancy removed with the tumor shown in figure 2

be cut into. The encapsulated solid tumor must be differentiated by frozen section, because often in young and in older women the larger tumor may be a fibroadenoma or a sarcoma. In the benign tumor the breast can be saved. In the malignant tumor the breast and the major pectoral muscle must be completely removed. The direct incision into breast tumors is necessary now

in far fewer cases, more often is the gross pathologic appearance of a blue-domed cyst or a distinctly encapsulated tumor so obvious that a frozen section is only confirmatory of the naked-eye appearance

I will reproduce here the illustrations of two cases that represent two distinct clinical types. One was clinically benign, a case in which the tumor was excised by cutting through normal breast, the seat of pregnancy hypertrophy. There was a difference of opinion on the frozen section at the time of the operation, and for this reason the patient was given immediate irradiation over the axilla without irradiation of the wound. There has been a difference of opinion on the interpretation of the sections among my own associates and at every meeting for the microscopic demonstrations held at the Surgical Pathological Laboratory of the Johns Hopkins Hospital since. This patient has been well now more than two years and has had a second pregnancy and normal delivery. During the second pregnancy four or five nodules appeared above the scar in the breast. These were not skin metastases but little breast tumors from 2 to 5 mm in diameter. They disappeared temporarily after the birth of the child. The child was weaned and then when the menses appeared, the tumors returned for a few weeks and disappeared again.

This patient (fig 1) has no sign of any disease in either breast or other part of the body today, in spite of which there is a minority in my own laboratory who still interpret the microscopic sections as malignant, and the majority of those who restudied these sections during the microscopic demonstrations held three times a year still cling to the diagnosis of malignancy. One of the special workers in the laboratory has reviewed most thoroughly all the tumors of the breast removed during pregnancy and during lactation and compared them with this case. He is still of the opinion that this case must be interpreted as malignant in spite of the fact that the patient is well more than two years after the removal of the tumor only and irradiation of the axilla only.

In spite of their larger experience with these borderline tumors, the best pathologists still disagree, but when they do so the patients live. Therefore, if good pathologists disagree it is fair to the patients to restrict the operation to the removal of the tumor. There is no objection to irradiating the axilla and protecting the wound of the breast while the decision of the pathologists is being awaited, and there is no objection—if there is disagreement—to finish the course of irradiation over the breast. I myself was so convinced that this case was pregnancy hypertrophy that I gave no more irradiation. I stopped her nursing after both pregnancies in order not to excite further growth in other areas of benign adenoma of the breast.

Figure 1 was taken about one year after the birth of the child when all examinations were negative, except a small tumor, outlined in ink on the forearm, which was removed in June 1932 and proved to be a benign nerve sheath tumor. Later, with the second pregnancy as already reported nodules appeared in the periphery of the breast above the scar.

Figure 2 shows the good margin of uninvolved breast tissue in pregnancy hypertrophy removed with a central zone of nonencapsulated tumor tissue. The tumor tissue is smooth while the breast is faintly lobulated and projects above.

I felt this tumor in the patient's breast two years before her marriage. It was freely movable and about

the size of a five cent piece (21 mm). I advised its removal because of the danger of its giving her trouble if she became pregnant and warned her of the danger of losing her breast should she have this tumor removed during pregnancy or lactation, because many pathologists would diagnose it cancer. She had a second, smaller, tumor in the left breast, which disappeared before she was married.

Figure 3 is a microscopic section from the center of the tumor removed. It shows the increased fibrous stroma of the old fibro-adenoma and tremendous cell proliferation of the lobule of the old fibro-adenoma.

Figure 4 shows a section from the junction of the old fibro-adenoma and the breast, the seat of pregnancy hypertrophy.

Figure 5 is an area in the fibro-adenoma which influences many pathologists to the diagnosis of malig-

Fig 7 (case 2)—Breast suggestive of malignancy; retraction of nipple shown is intermittent favoring benignity

nancy, especially when they compare it with figure 6, which is a section of the normal hypertrophy of pregnancy.

I have been familiar with these typical microscopic pictures in distinctly encapsulated tumors removed from the breast during pregnancy or lactation. In not a single instance have I been able to find pictures in these lactating adenomas that resembled the microscopic picture of cancer in the breast during pregnancy or lactation. In practically all malignant tumors during pregnancy or lactation the axillary glands have been involved, and in more than 75 per cent in which the glands were involved the patients died of cancer. Billroth has called attention to the fact that adenomas of the breast are subject to the same changes as is the breast during pregnancy and lactation. But there is no complete study yet published with proper illustrations on the microscopic pictures of breast tumors during pregnancy and lactation and of their differentiation from malignant tumors.

I have no evidence that malignant tumors in the breast during pregnancy or lactation arise in preexisting adenomas of any type

The second case to be reproduced here (figs 7 and 8) was a diffuse tumor of the upper hemisphere of the right breast too large for complete excision. It was partially removed; numerous frozen sections were made and the operator, my associate Dr L. Clarence Cohn, decided that it was benign and saved the breast. There was no postoperative irradiation. There was a difference of opinion during the operation and has been since. It has now been more than three and one-half years, the patient is well and the breast palpates and transilluminates normally. During this period I have been making in the laboratory a complete restudy of a type of breast tumor that I have called comedo-adenocarcinoma.

Fig. 8.—Section of tumor in breast shown in figure 7 interpreted as benign comedo-adenoma by the operator. Incomplete removal. No recurrence in the remaining breast three and one-half years later. No irradiation before or after operation. In the upper half are typical comedones; the lower half of the picture shows intraductal papillary adenoma. No evidence of cancer.

and now call comedo-adenoma. When this tumor is of a pure microscopic type there has never been metastasis to the axilla, never death from cancer. But this comedo-adenoma may be associated with fully developed cancer, and then it acts like fully developed cancer with the same prognosis. The case shown in figures 7 and 8 is, under the microscope, the benign type of comedo-adenoma. I shall show only one microscopic picture here (fig. 8), because I expect to report fully on this case later in the *American Journal of Cancer*, as I delivered a paper on this subject before the American Society for Cancer Research in Toronto in May.

Figure 7 pictures clinically Dr Cohn's case. The patient was a woman at the cancer age, and there were certain things in the clinical picture that made Dr Cohn suspicious of a malignant growth, and for this

reason he explored. The retraction of the nipple shown in the photograph was intermittent. The mass occupying the upper hemisphere of the breast varied in size. The patient was certain of this. When Dr Cohn explored the tumor it was solid, diffuse and without cysts, but there were numerous comedos of granular debris which could be expressed from the surface of the tumor everywhere. There was no gross evidence of cancer—only comedo-adenoma. Nor, in the section (fig. 8) was there evidence of anything but comedo-adenoma or what is known in the literature as duct cancer.

I urge every one who reads this article to read also a paper by Campbell² on chronic cystic mastitis. Campbell gives the best discussion of all the literature on the subject. There is also a splendid review of the early literature on chronic cystic mastitis by my associate Dr Charles F. Geschickter.³ The difficulty in presenting borderline tumors is, first, space for illustrations and secondly, one must wait at least two or three years to ascertain the result.

The only way for surgical pathologists to become familiar with this group so difficult to diagnose is to study the microscopic sections repeatedly as the patient is followed.

My experience to date seems to justify my making the statement that when a surgeon operates on a clinically benign tumor that is small enough he should excise the tumor by cutting through healthy tissue and then, after its removal, bisect it in his hand and make frozen sections. If in doubt as to a malignant condition the wound should be closed. If high voltage roentgen therapy is available, radiation over the axilla should be done. If the pathologic reports from a number of pathologists come in uniformly that the tumor is benign or by the majority that it is benign nothing further should be done. If the pathologists agree as to malignancy, or only the majority of them, there are two courses—either finish a thorough preoperative course of irradiation and then wait the proper time and perform the complete operation for cancer or stop irradiation, wait a proper interval and then perform the complete operation for cancer. At the present time the majority of the best trained and experienced surgeons, pathologists and radiotherapists are of the opinion that complete operation for cancer should be performed on the doubtful breast tumor as soon as the pathologic report of the consulting group is received agreeing with, or with a majority opinion in favor of, malignancy.

My own opinion at the present moment, I appreciate is a minority opinion. But I am gathering evidence in its favor and I propose to put this evidence before my colleagues as quickly as possible. I have sufficient evidence, however, to justify this conservative advice about borderline tumors, especially those of the type that can be excised completely as illustrated in the case in figures 1 and 2. In cases of the type of the second case illustrated in figures 7 and 8, the conservative operation should be reserved for those special clinics which have had large experience in the treatment of borderline tumors of the breast; otherwise, the complete operation for cancer of the breast should be performed at one sitting.

ABSTRACT OF DISCUSSION

DR. IRVIN ABELL, Louisville, Ky More tumors requiring biopsy are being seen than ever before I have used biopsy with immediate examination of the frozen tissue sections since 1917, feeling that the interpretation of the pathologist with the microscope would be superior to one's own naked eye interpretation regardless of how much one correlates the experience of the two When the biopsy proves the tumor malignant, my routine practice has been to close the wound and immediately proceed with a radical mastectomy I am aware that in some quarters there is a disposition to vary from this treatment, namely that when the tumor is small and is removed by biopsy and proved to be malignant, it may be treated safely with radium or x-rays I have had no experience with this treatment but I have had come into my service five patients who have been so treated elsewhere a small tumor was removed and radium was implanted in the wound with subsequent irradiation after the healing of the wound All five had recurrences in the breast and three had axillary metastasis The result of complete mastectomy in the presence of a malignant condition has been so excellent as to compensate for the loss of the breast The retention of the breast in the presence of a known malignant condition, to be treated subsequently with radiation, is fraught with danger, particularly if the practice becomes general The wide variation in equipment in technic, in dosage of irradiation is such that it is a difficult matter for one to draw correct conclusions as to the evaluation of the method. If every one had the machine to which Dr Bloodgood referred, with a 200 kilowatt power, and if there was a standardized dosage and technic, it might possibly be safe to attempt treatment along this line, but it is evident that the treatment that may be safe in the hands of well equipped, well trained personnel conceivably is not a safe thing to be adopted by the general profession In my earlier experience I endeavored to preserve the breasts of these patients with so-called borderline tumors One of them came back within eight months with recurrent growth in the breast, and two others came back still later with recurrences in the breast and axillary node metastasis After that I came to the conclusion that a tumor is either benign or malignant and if the pathologist could not assure me of the malignancy of a given growth and wasn't positive as to its nonmalignant nature the patient would be safer with a simple or a conservative mastectomy in order to prevent local extension and recurrence

DR. MAX CUTLER Chicago Dr Bloodgood raised several important questions on radiation therapy of mammary cancer Difference of opinion exists on this subject which because of inadequate data is at present a subject of controversy even among those who have had the greatest experience with this problem I should like to make the following observation Three major difficulties are encountered in the radiation treatment of mammary cancer 1 The extensive surface area that must be regarded as potentially involved, regardless of how early the lesion appears to be on clinical examination 2 The relative radioresistance of most malignant tumors of the breast 3 The difficulty and uncertainty of effective irradiation of the axillary lymphatic glands According to the latest conceptions of dosage and technic, the amount of radiation that is necessary to sterilize the more radioresistant forms of mammary cancer is such as to preclude the subsequent radical surgical removal of the breast with safety Thus the present development of radiation leads to a more effective treatment of mammary cancer when radiation alone is used rather than when radiation is combined with surgery The use of preoperative radiation in moderate doses can be defended on the basis that there exists a small group of carcinomas of the breast that is moderately radiosensitive Clinical and pathologic evidence is available to demonstrate that this small group can be sterilized by a dose of radiation that can be followed safely by the radical surgical operation. I utilize preoperative radiation under two circumstances 1 In lesions of clinical borderline operability 2 In lesions in which the clinical setting and microscopic evidence when available indicate the presence of a highly malignant anaplastic carcinoma particularly in younger women Most

statistical evidence attempting to prove the value, or lack of value, of prophylactic postoperative irradiation is contradictory, subject to numerous fallacies, and insusceptible of withstanding critical analysis When the complete radical operation is performed on an early localized carcinoma of the breast and the axillary lymphatic glands are not invaded, it is difficult to defend the routine use of prophylactic postoperative irradiation, although this procedure has been generally adopted by most clinics Since postoperative irradiation can be administered with complete safety and its use entails no risks or delays most radiologists advise this procedure as a precaution When microscopic examination of the tumor indicates a highly anaplastic carcinoma or when the axillary lymphatic glands have been invaded there is considerable evidence to indicate prophylactic postoperative irradiation and I utilize it under these circumstances Because of the fact that when irradiation precedes surgery the dose of radiation must be reduced, it is entirely inadequate to control the more radioresistant forms of mammary cancer Because of this fact the restriction of the extent of the surgical procedure is entirely unsound and dangerous Under no circumstances should the extent of the radical operation for mammary cancer be reduced either because the lesion is small or because irradiation is combined with the surgical procedure

DR. J. C. BLOODGOOD Baltimore I thank Dr Abell and Dr Cutler I am sorry they didn't read to you the letter I wrote them in which I said that if they could possibly differ with me I wished they would I was trying to bring the borderline tumors before the profession At least I have no evidence that, if there is a little delay between the removal of this clinically benign tumor and the radical operation, if it is proved to be malignant delay is dangerous I cannot give the evidence in the time allotted here, but I have evidence to prove the statements I have made Therefore the pathologists throughout this country must be given an opportunity to prepare themselves to recognize the borderline tumors that are malignant Not every hospital can be furnished with such a trained pathologist Therefore the operators when their own pathologists are unable to diagnose the breast tumor, must send it to two or more of these diagnostic clinics for their view and when two or more such diagnostic clinics differ the operator may conclude that the tumor is benign During this period when sections of the borderline breast tumor are submitted to other pathologists the axilla of the patient can be treated with high voltage roentgen therapy and if there is further delay after ten days the breast can be irradiated If the positive diagnosis of malignancy comes in then radiation treatment can be stopped and after an interval of one week or ten days the complete operation for cancer performed

The Fertile Period in Monkeys—The female monkey which is the only animal to show a true and regular menstrual bleeding has a menstrual cycle lasting on the average from twenty-seven to thirty days (Corner, E. Allen, Hartman, Joachimovits, Spiegel and Zuckerman) In contrast with other animals which have a distinct heat and as a rule only copulate during this time, the female monkey allows access to the male at all parts of the menstrual cycle but she does not become pregnant after every coitus This animal, therefore, also manifests a periodic alternation of fertility and sterility Hartman, who carried out a lengthy series of experiments on a large and well supervised colony of monkeys to determine the boundary between the fertile and the sterile periods found that out of 420 acts of intercourse which took place on all days of the menstrual cycle, only 52 led to pregnancy and that out of these 52 conceptions 49 took place between the eleventh and sixteenth days inclusive Hartman found a fertility rate of 25 per cent on the eleventh day, 11 per cent on the twelfth and thirteenth days and 25 per cent on the fourteenth day There is in fact, such a sharp line between the sterile and fertile days of the monkey that Hartman is perfectly justified in saying that these animals have a 'safe period'—Knaus Hermann Periodic Fertility and Sterility in Woman Vienna, Wilhelm Maudrich 1934

THERAPEUTICS OF THE INTRAVENOUS DRIP

FURTHER OBSERVATIONS

HAROLD THOMAS HYMAN, M.D.

AND

ARTHUR S. W. TOUROFF, M.D.

NEW YORK

In a previous report¹ dealing with the influence of velocity on the response to intravenous injection, the physiologic advantages of the slow intravenous drip were stated. Later, a convenient apparatus for the clinical use of the drip was described together with details for preparing sets and solutions.² In analyzing 100 consecutive requests for these sets, the therapeutic indications³ included the treatment of (a) hemorrhage (b) shock, (c) the infectious medical and surgical diseases (d) the prevention of complications in extensive or shock-producing surgical procedures, (e) the prophylaxis and treatment of thyrotoxic crises (f) the

(h) the treatment of exogenous poisoning. In the thirty months since January 1932, 9,471 sets have been employed in the hospital—an average of ten sets daily. The frequency with which the sets have been used is sufficient proof of the widespread adoption of this method and its great utility.

The present communication deals further with the therapeutics of the intravenous drip as illustrated by a series of 1,000 consecutive experiences.

AS A PROPHYLACTIC AND SUPPORTIVE IN VARIOUS SURGICAL CONDITIONS

There has been an increasing tendency on the part of surgeons to use the drip as a supportive during the critical period of the operative manipulation, or as a prophylactic against complications. Drips for these purposes were started before the patient came to the operating room, during the course of the operation, or immediately after the patient was returned to the ward.

A *In Appendicitis with Peritoneal Complications*—Sixty-six patients who were admitted to the hospital with acute appendicitis complicated by peritonitis or local abscess formation were given prophylactic intravenous drips. The clinical course was often complicated further by intestinal obstruction, multiple intraperitoneal abscesses, subphrenic collections of pus or sepsis. Many of these patients were admitted with moderate or marked temperature elevation and occasionally with chills. Despite this, Dr. Harold Neuhof, a pioneer in intravenous therapy,⁶ had no hesitancy in employing the drip. In instances in which postoperative chills or elevation of temperature occurred a search for complications was carefully instituted before the culpability of the drip was considered. With the onset of complications or spread of infection, the patient's welfare necessitated the continuance of the drip as a therapeutic endeavor. This was often rewarded by recovery in the presence of grave prognostic signs.

B *In Surgery of the Gastro-Intestinal Tract*—The prophylactic intravenous drip has also been extensively used by Dr. A. A. Berg⁷ in formidable procedures on the gastro-intestinal tract. Two hundred and eighteen patients were included in this group. One hundred and thirty-six were subjected to resection of the stomach, duodenum or jejunum. Thirty-four patients had cancer of the stomach, and forty-three had peptic ulcers. In sixteen, perforation or penetration of the bowel had occurred and eight had secondary resections for gastro-jejunal ulcers. Four of the group had had massive hemorrhages, there were eight with pyloric obstruction and two with pancreatic abscess, as the result of penetration or perforation of peptic ulcers. One patient had a complicating cirrhosis of the liver, another a mitral stenosis, and a third diabetes mellitus. In the majority of instances Dr. Berg was able to accomplish resection of the bowel and anastomosis.

Eighty-two patients had lesions involving the lower part of the bowel and of these seventy had carcinoma of the colon, sigmoid, cecum or rectum. Seven patients had intestinal obstruction from various causes and the rest had miscellaneous conditions such as stab wounds, regional ileitis, diverticulitis, ulcerative colitis, intussusception, perforation by foreign bodies or volvulus.

In the majority of the patients with carcinoma of the large bowel, Dr. Berg successfully performed resection.

Fig. 1—Complete assemblage of intravenous drip showing the set in use with the arm of the patient strapped to a fracture board.

alleviation of postoperative complications such as ileus, gastric dilatation, vomiting and anuria (g) the treatment of various metabolic and toxic conditions such as the alimentary toxicosis of infancy,⁸ dehydration resulting from uncontrollable vomiting or intractable diarrhea, urinary suppression and diabetic ketosis, and

and anastomosis. The drip was employed by him in several ways. In the less complicated cases it was started during or just after the operative procedure to tide the patient over the first few postoperative hours or days and to maintain nutrition, so that oral feeding might be minimized. In patients who were malnourished or anemic, the drip was used preoperatively to build up the general resistance and to correct the anemia.

Fig. 2—The metal case container devised by Dr. Joseph Turner and provided with slots to permit the entrance of steam during autoclaving.

by the introduction of citrated or whole blood. This type of preparation enabled Dr. Berg to execute major procedures in many patients who, on admission, seemed impossible surgical risks and helped to support others beyond the critical period.

C In the Surgery of the Chest and Nervous System—In similar fashion, Drs. Harold Neuhof and Ira Cohen, respectively in charge of surgery of the chest and the nervous system, employed the intravenous prophylactic drip as a routine in all serious exigencies that arose in these special fields. In the thoracic service it was almost an invariable custom to start the drip in the operating room in thoracoplasty, pneumotomy, lobectomy, or extensive rib resection in adults, and with simpler suppurative lesions of the pleurae and lungs in infants and young children.

In the surgery of the brain and spinal cord, hypertonic dextrose solutions were of added value in decreasing intracranial tension.⁸

D In Surgery of the Biliary Passages—There seemed to be an increasing tendency to employ the drip in procedures involving the liver and biliary passages. The coexistent disturbances in carbohydrate metabolism, the tendency to bleed, especially in the presence of jaundice, and the metabolic hyperpyrexia that is not uncommonly seen following surgical manipulation in this field furnished ideal indications for the use of a prophylactic drip. In secondary procedures on the biliary passages, the drip was employed prophylactically in virtually every instance.

E In Genito-Urinary Surgery—In genito-urinary surgery, Dr. Beer and his colleagues used the drip prophylactically most commonly in an attempt to maintain adequate urinary secretion. Reflex oliguria and anuria with resultant azotemia are frequent and serious complications following manipulation of the genito-urinary passages. These were experienced particularly in elderly patients whose kidneys had been damaged by prolonged urinary retention or infection. Intravenous dextrose exerted a beneficial diuretic action.

F In Thyroid Surgery—In surgery of the thyroid gland Dr. Lewisohn used the prophylactic drip in the severe or complicated cases of exophthalmic goiter. It has been our practice^{9,10} however, to use the drip as

a routine in all operations on the thyroid gland, because of the uncertainty of predicting the occurrence of thyrotoxic storms.

G In the Surgery of Diabetes—In surgery on diabetic patients, the management of the metabolic condition was greatly facilitated by the use of the prophylactic drip. The risk in operating on these patients was usually out of all proportion to the actual extent of the surgical procedure. Simple postoperative complications, particularly vomiting, may readily produce a ketosis. A valuable method of preventing unfortunate sequelae was the liberal supply of fluid, dextrose, saline solution and insulin by the prophylactic intravenous drip.

H In Surgery of Hemorrhagic Diseases—Patients who had hemorrhagic diatheses, from whatever cause and who were subjected to surgical procedures were given the advantage of the drip. The introduction of citrated or unmodified blood not only replaced the lost blood but also aided in increasing coagulability. Dr. Nathan Rosenthal, who is in charge of the hematologic cases, constantly made use of the drip for these purposes.

USE OF THE INTRAVENOUS DRIP FOR COMPLICATIONS THAT OCCUR FOLLOWING SURGICAL PROCEDURES

In a previous paper⁴ the therapeutics of the drip in the actual treatment of surgical complications was amply described and needs little elaboration. In the management of hemorrhage, shock, postoperative vomiting, gastric dilatation, ileus, anuria, oliguria and sepsis, indications were clearly defined and the drip was of incalculable value.

When these symptoms arose, the drip was also employed advantageously for the introduction of drugs and biologicals. In shock or collapse, the value of the drip was enhanced by epinephrine or epinephrine. In postoperative ileus, the introduction of ampoules of pitressin into the rubber tubing above the needle was effectively carried out. Acidosis following vomiting, in diabetic and nondiabetic patients, was treated by the introduction of alkali or dextrose together with adequate amounts of insulin. In sepsis, whole blood was used nonspecifically and, if a specific antibody was available the serum was dripped in constantly so that enormous dosages were introduced with little risk or reaction. In the thyrotoxic storms of exophthalmic

goiter iodides were added directly. In two instances of acidosis resulting from the use of massive doses of ammonium chloride or sodium phosphate, sodium

bicarbonate administered intravenously promptly corrected the metabolic disorder

In traumatotherapy the drip found a great sphere of usefulness in combating both shock and hemorrhage. In skull injuries, the intravenous introduction of hypertonic solutions accompanied by repeated lumbar taps aided in the adjustment of pressure relationship within the cranial cavity.⁸

Fig. 4—A close view of the method of maintaining the needle in the vein by means of sterile adhesive tape

In extensive burns, drips of dextrose with saline and blood were of the greatest value in correcting dehydration and in combating anuria.

THE USE OF THE INTRAVENOUS DRIP IN INTERNAL MEDICINE

Many of the uses of the drip in internal medicine have already been indicated in the discussion of the surgical procedures. In the management of ketosis in diabetes, in the treatment of azotemia in nephritis, in the dehydration that occurs with toxic vomiting or intractable diarrhea in infants⁶ or adults in hemorrhage and in the hemorrhagic diatheses the indications and procedures were self evident. In poisonings with carbon monoxide, barbiturates, morphine, mushrooms, arsenic, colocynth, corrosive mercuric chloride and the cholemia that resulted from cinchophen poisoning the drip was often of great value. In one instance of bromism with cerebral symptoms, the chloride in the drip was utilized to replace the bromide ion.

There is great promise in the extension of the use of the drip in the introduction of massive doses of specific serums and drugs. With specific serums for example, it was a comparatively simple matter to introduce daily from 200 000 to 300 000 units of pneumococcus tetanus or diphtheria antibody in the course of a continuous drip. Serum reactions were greatly minimized by the slow introduction of diluted agents.

With Chargin and Leifer,⁹ we have conducted experiments in massive chemotherapy. Twenty-five male patients with primary seropositive or secondary syphilis received an average of 4 Gm of neoarsphenamine in a period averaging five days. No serious or permanent early or late parenchymal changes occurred in these patients, though febrile reactions were common and at times alarming. Wassermann negativity was obtained in 95 per cent of the nineteen cases followed beyond the critical period of three months, though neither bismuth nor mercury compounds were employed. This work is still in the experimental stage. It is extremely suggestive and may prove of great value.

UNTOWARD REACTIONS OF THE DRIP

Drips were frequently maintained for several days and in one instance a drip ran for three weeks. Many patients had intermittent drips, so that the total number of sets used far exceeded the number of patients. Despite this, difficulties arose on only thirty-eight occasions, usually because of chills or febrile reactions.

A Chills During Transfusion—Chills followed transfusion eleven times, eight by the citrate and three by the direct method. Citrate transfusions were used proportionately more frequently than direct transfusions. Once a chill occurred with citrate transfusion and then the direct method was employed without chill. Contrariwise in one instance in which the direct method was followed by a chill, the citrate method was used without reaction. The citrate method, introduced by Dr. Richard Lewisohn¹⁰ at our hospital in 1915, is so simple that we find no valid reason for recommending the more complicated direct method. The citrate transfusion was often performed without the patient's knowledge and did not require the complicated set up or the technical skill necessary with the direct methods. To our knowledge, the direct method possessed no positive advantages, and reactions were no less frequent.

B Chills Resulting from the Underlying Pathologic Process—In fifteen instances, chills occurred during the course of a drip but seemed the result of the underlying pathologic condition. In six cases each of extensive genito-urinary infection, or peritoneal involvement, rigors occurred. Often the drip had run for many hours before or after the chill. In one instance each the hyperpyrexia probably was caused by thyrotoxicosis in exophthalmic goiter,¹¹ the terminal febrile elevation of diabetic coma¹² or the onset of pneumonia.

C Chills Resulting from Technical Errors in the Preparation or Administration of the Drip—There remained twelve instances of chills resulting from the drip. In eight of the twelve, the chill occurred at the onset of the drip, probably owing to contamination of

Fig. 5—The same as in figure 4 with most of the adhesive tape removed

the solution by some pyrogenic substance.¹³ In four other instances the chill occurred during the course of the drip. These reactions ceased when analytic reagent sodium chloride, packed in individual stoppered bottles, was substituted for chemically pure sodium chloride, distributed in small barrels, and when a carboy

used as a reservoir for the triple distilled water was thoroughly cleansed. In each instance it was thought that pyrogens had been introduced by these apparently trivial lapses in vigilance. We are in complete agreement with our colleagues Drs. Lewisohn and Rosenthal³ who state in speaking of the reactions following citrate transfusion, that these occurrences are preventable and invariably due to some technical error. Safety is obtained only by eternal vigilance and in our institution we are particularly indebted to Miss Anna Koch, who is in charge of the central room for the preparation of intravenous sets, and to Dr. Nathan Rosenthal, who supervises this department. Even with technically perfect sets, however, reactions will occur unless the clinician is equally careful in performing his end of the set-up of the drip and the current craze for speed will be penalized by reactions, particularly when the vehicle contains pyrogenic substances.

DEATHS ASSOCIATED WITH DRIP THERAPY

More important than the febrile reactions and chills, which in themselves did not seriously or permanently jeopardize the patient's chances for recovery, were two instances in which death occurred.

CASE 1—A woman with exophthalmic goiter, who was admitted during a severe thyroid storm, received the drip on two successive days, following which she was given 125 cc of citrated blood. The drip had been administered with impunity, but following the citrated blood she had a chill lasting forty minutes, her temperature rose to 108 F, and she died within twenty-four hours.

CASE 2—A man with a cancer of the rectum who had had a resection of the bowel and a permanent colostomy, was given a postoperative prophylactic drip for four days; he did well for two weeks, and then a severe diarrhea developed and the patient became dehydrated. The drip was resumed and was followed by a severe chill and a rise in temperature to 108 F. Death occurred four hours later. Autopsy showed no cause of death.

The history in each of these instances strongly indicates that the drip might have contributed to the fatal termination. While terminal hyperpyrexia occurs as part of the clinical syndrome in thyroid "storms,"¹¹ no such explanation can be afforded in the carcinoma fatality.

MISCELLANEOUS NOTES

Though many of our patients were desperately sick and often moribund, at no time did we encounter any circulatory complications that might have resulted from the introduction of the fluid. Local pain and discomfort were frequent complaints and usually responded to changes in position or to sedatives or narcotics. There were no significant local inflammatory processes in the skin or the veins.

As the drip requires frequent adjustment, the patients must be seen from time to time to regulate the rate of flow, add solution or change the position of the arm. This frequently imposed an extra burden on the nursing facilities, particularly when the ward services were active. Under these circumstances, if special nursing was not possible, the drip was removed during the night hours and resumed during the daytime when more members of the staff were in active attendance.

Physicians who practice in outlying communities and who lack hospital facilities for the sterilization of apparatus and solution may take advantage of the ingenious sets that have been commercially devised and that can be purchased and stored indefinitely.¹⁴ These

sets are easily assembled and are free from pyrogenic substances. In our limited experience these sets have been completely satisfactory.

For the benefit of the many clinicians who harbor the fear that an intravenous drip might tend to elevate blood pressure and thus cause or perpetuate bleeding, it is important to note that no such occurrence was encountered in the entire series.

During the course of prolonged intravenous infusions the patients should frequently be examined for peripheral edema or edema of the lung. At times these may be due to excessive amounts of salt under which circumstances distilled water may be substituted with from 5 to 50 per cent dextrose. If the edema is severe, the drip must be discontinued temporarily and the patient placed on limitation of fluids or mercurial diuretics.

ABSTRACTS OF CASES ILLUSTRATING THE VALUE OF THE DRIP

The value of the drip may be emphasized by citing briefly illustrations of its use in specific instances in which immediate recovery occurred.

CASE 3—In a patient with tonsillitis an acute glomerulonephritis and uremic coma the drip ran for three days, following which the patient had clyses for four days. Four weeks later the patient had a tonsillectomy without any difficulty.

CASE 4—A patient had a subacute yellow atrophy following the use of cinchophen derivatives. She was admitted with jaundice and fever. The drip ran for two days until the acute symptoms disappeared.

CASE 5—In a patient with a carcinoma of the sigmoid, a colostomy was attempted under spinal anesthesia and shock ensued. The drip was started in the operating room, ephedrine and epinephrine were added to the fluid, and artificial respiration was instituted for the respiratory paralysis. The operation was completed the drip continued to run for two days and the patient made a complete recovery.

CASE 6—A diabetic patient had a duodenal ulcer with pyloric obstruction. Vomiting was persistent and acidosis developed. A drip of dextrose with insulin was given and at the end of three days the patient was in excellent condition. Shortly thereafter the patient was readmitted with hematemesis from the ulcer. Three transfusions of citrated blood were administered, a gastro-enterostomy was performed, and a postoperative prophylactic drip was used for two days.

CASE 7—A child, aged 4 years, suffered extensive first and second degree burns of the face, chest and abdomen, with marked toxemia. A drip was instituted for two days and citrated blood with dextrose was introduced with gratifying results.

CASE 8—A pregnant woman was admitted with the symptoms and signs of an acute surgical condition of the abdomen, shock and persistent vomiting. Because the indications were not clear, the surgeons wisely decided to temporize, and the drip was instituted for twenty-four hours. Following this the symptoms abated and the patient recovered and was discharged.

CASE 9—In this case definite indications for operative intervention abated after the use of the drip for a few days. The patient had a pyloric obstruction from a duodenal ulcer and was admitted with persistent vomiting. He refused operation and was placed on a drip for three days, after which the vomiting subsided and the obstruction disappeared.

CASE 10—A man with a pyelonephritis was admitted in uremia with a urea nitrogen of 108 mg per hundred cubic centimeters of blood. The drip was continued for three days, the urea nitrogen fell to 46 mg per hundred cubic centimeters and the patient recovered sufficiently to be discharged from the hospital.

CASE 11—A patient had a combination of pernicious anemia, diabetes mellitus and cirrhosis of the liver. He was admitted in coma that was probably the result of a combination of hepatic insufficiency and ketosis. The blood sugar was 300 mg. A drip ran for two days and the patient recovered from the acute episode.

¹⁴ The Titus intravenous infusion apparatus (J. A. M. A. 100:1104 [April 8], 1933) and the sterile dextrose in physiologic solution of sodium chloride in vacoliter containers prepared by the Don Baxter Intravenous Products Corporation (J. A. M. A. 102:1154 [April 7], 1934).

CASE 12—A patient injured in a traffic accident had a contusion of the lung with a pleural effusion and marked shock. The drip was instituted for two days and recovery followed.

CASE 13—A patient presented a complicated clinical picture of diabetes mellitus, hypertension and a twisted ovarian cyst. A drip of dextrose and insulin was started before operation and was followed in an hour by a chill and a temperature of 102 F. The drip was discontinued but after operation was resumed again and the patient made a complete recovery. Shortly thereafter she was readmitted with an incarcerated umbilical hernia and intestinal obstruction. Vomiting was persistent. A drip of dextrose and insulin was again instituted and was continued through the hernioplasty and for two days later, after which convalescence was uneventful.

CASE 14—A man with a tubercular bladder and prostatic hypertrophy was admitted in uremia. The drip ran for four days and the patient's condition was sufficiently improved so that the presacral nerves could be resected and a suprapubic cystostomy performed, after which a normal convalescence occurred.

CASE 15—A patient entered the hospital with a toxic hepatitis and gastro-enteritis from arsenical intoxication and a syphilitic iritis. A drip of 10 per cent dextrose with insulin was administered for four days and recovery followed.

CASE 16—This illustrates one of the several instances in which, following acute appendicitis with peritonitis, postoperative ileus developed. A drip was started, the stomach drained by a Levin tube and the ileus controlled, and later an intraperitoneal abscess ruptured spontaneously through the wound.

CASE 17—This is also illustrative of several instances in which an incarcerated hernia caused vomiting and distention. The drip was started, the hernia was manually reduced, the bowels again functioned and, after a free period of a week, a hernioplasty was performed.

CASE 18—This was one of several instances of emergency surgery in diabetes. An acute cholecystitis with cholelithiasis developed in a patient. The blood sugar was 270 mg per hundred cubic centimeters and acetonuria was marked. A drip of dextrose and insulin was started, a cholecystostomy and drainage was performed, the drip was continued for four days, after which the patient recovered and the diabetes was easily controlled.

CASE 19—Another surgical diabetic patient was admitted in diabetic coma and with a carbuncle of the lip. The blood sugar was 400 mg per hundred cubic centimeters, the carbon dioxide combining power was 11.5 volumes per cent, and acetonuria was marked. A drip of dextrose and insulin ran for two days. The blood sugar fell to 60 mg, the carbon dioxide combining power rose to 57 volumes per cent, the carbuncle of the lip responded to conservative treatment, and the patient was discharged.

CASE 20—This case illustrates the control of the vicissitudes that occur in elderly patients with prostatic hypertrophy. This patient had a first-stage prostatectomy followed by profuse hemorrhage. A drip was given with epinephrine and caffeine, and citrated blood was later introduced. The drip ran for four days, following which the second stage was done with an uneventful convalescence and recovery.

CASE 21—This illustrates another use of the drip in the treatment of poisoning. The patient had barbiturate intoxication and remained in coma for two days, after which the drip was started. In sixteen hours the patient regained consciousness and made a complete recovery.

CASE 22—This is one of several instances in which azotemia occurred during the course of operative intervention on the biliary passages. The patient had a cholecystectomy, and a postoperative prophylactic drip was run for a day and a half. After the cessation of the drip the blood urea nitrogen rose to 66 mg per hundred cubic centimeters and the temperature to 103 F. On the sixth day the patient was stuporous and the drip was resumed for four days, during which time the temperature and urea nitrogen fell to normal.

CASE 23—This illustrates an unusual instance of acidosis, probably from the excessive use of ammonium chloride. Following a suprapubic prostatectomy for fibro-adenoma of the prostate, the patient's blood pressure fell from 160 to 100, he became stuporous and signs of acidosis developed with 14 volumes per cent of carbon dioxide combining power of the blood. A drip

was run for twelve hours, beginning with sodium bicarbonate. The patient reacted thirty minutes after the institution of the drip and made a recovery.

CASE 24—A patient in whom the persistent use of the drip was rewarded by an extraordinary recovery had a common duct stone with jaundice, and a cholecystectomy and choledochotomy were performed. A postoperative prophylactic drip ran for three days. On the fifth day the patient went into collapse from an intraperitoneal hemorrhage, which later became infected. For the next three days the drip was used and citrated blood was added on two occasions. After an intermission of four days this therapy was again resumed for fifteen days. On the twelfth day a direct transfusion was performed, and a chill ensued. The transfusion was repeated without a chill and the patient went on to make a complete recovery.

CASE 25—The use of the drip in preparing patients for operation is well illustrated in a patient who had a bleeding and penetrating duodenal ulcer. For nineteen days the patient was given daily drips and two citrate transfusions. A subtotal gastrectomy was then performed and a postoperative prophylactic drip was started and fortified with a pint of citrated blood. The drip ran for four days, during which time another pint of blood was introduced, and the patient recovered.

CASE 26—This is one of several complicated renal cases in which bilateral calculi occurred. A right nephrostomy and left ureterolithotomy were performed. The blood urea nitrogen rose on the first postoperative day to 53 mg per hundred cubic centimeters. A drip was run for two and a half days and the patient was markedly improved. On the thirteenth postoperative day a pain in the left side and anuria developed. The drip was resumed for four days. Four months later a right nephrectomy was done, following which postoperative vomiting occurred. After a drip that ran for a day and a half, the symptoms were alleviated.

SUMMARY

The intravenous drip has won a permanent place in therapy in our institution. The use of 9,471 sets in thirty months, or of ten sets daily, gives numerical testimony on this point. These figures are supported further by a comparison of the number of intravenous and hypodermoclysis sets that have been used in this period. In 1932, 3,235 intravenous sets were ordered, and 2,157 clysis sets; in 1933, 4,287 of the intravenous sets were used and but 1,539 subcutaneous sets. To date in 1934, 1,949 intravenous sets have been used, and only 322 clysis outfits. In comparison with hypodermoclysis, the intravenous drip has the advantage of more certain absorption, greater adaptability, less discomfort to the patient, and the possibility of adding drugs and whole blood directly into the circulation. At the seemingly slow rate of 2 or 3 cc. per minute, the drip will introduce daily between 2,500 and 4,000 cc. of fluid and may be continued for several days or even weeks, as in patient 18, who received a drip for twenty-four days.

Once the drip is in operation, it is impressive to observe the ease of management of extremely difficult and complicated conditions. By the single technical procedure the problem of nutrition and of the introduction of fluid, salts, drugs, blood and serum becomes automatic.

940 Park Avenue

ABSTRACT OF DISCUSSION

DR. T. G. ORR, Kansas City, Mo. This important means of therapy is growing in popularity. Continuous venoclysis has been emphasized very much in recent years. The work of Hyman and Hirschfeld has been especially important in introducing the term "speed shock," perhaps not of the term itself, but of emphasizing the importance of speed in giving intravenous solutions. They have shown conclusively that many solutions can be given safely if they are given slowly enough. There are four major dangers, perhaps not so great if given properly but nevertheless constantly present: (1) the immediate

reaction, (2) the possibility of overloading the circulatory tree (3) the production of edema, (4) the production of pulmonary embolism. Any one of those four, I believe, may happen, although perhaps not very frequently. Two or three deaths that occurred recently may have been caused by pulmonary embolism, secondary to continuous venoclysis. This led to experimental work, which has been carried out in the University of Kansas surgical clinic by Dr Mervin Rumold in animals, continuous venoclysis being given as long as the animal lived. He has done this work in several series of experiments with simple salt solution, dextrose in 10 per cent solution, a combination of the two, and by simply placing cannulas and needles in the vein. In every instance he found pulmonary involvement after experimental introduction of these solutions. There is a local irritation of the vein, in which a thrombus forms. Emboli break off and float into the lung. Experimentally, there is certainly definite danger in giving continuous venoclysis by the drip method. Solutions were given very slowly, the animals watched twenty four hours of the day, and inspected every hour to see that the solutions were running properly. In every single instance there were pulmonary complications. It is to be remembered that nature never intended feeding, watering and treatment to be given by vein and that the insult should be properly respected.

DR. PAUL TITUS, Pittsburgh. The indications presented for prolonged, slow intravenous medication seem to be many, but probably they are still incomplete. The advisability of terming this "intravenous drip" is questionable, however and I prefer Hendon's term, prolonged venoclysis," or that of Fantus, "phleboclysis." The solution does not drip into the vein, it runs in a steady, slow stream through the needle, even though a glass drip bulb is sometimes used to measure the rate of flow. Other instruments, such as the one devised in our clinic for several different types of intravenous injections of dextrose, have a valve instead of the drip bulb for this slow flow, and the term 'drip' may give an incorrect impression of the operation. Being convinced of the therapeutic value of the prolonged venoclysis, I should have liked to hear more about flow rates and total dosages. My colleagues and I have been interested in the intravenous use of dextrose solutions in pregnancy toxemia and gynecologic surgery. Clinicians are not dependent on prolonged venoclysis for this, as prolonged injection is not always necessary, but we have available single large therapeutic doses of dextrose (from 75 to 100 Gm.) that may be given faster than the prolonged venoclysis. For example, a 25 per cent solution should be given at 3 cc. per minute in an average sized adult to maintain the physiologic rate of Wilder and Samson, namely, 0.8 Gm per kilogram of body weight per hour, and weaker solutions proportionately faster. The proper rate may easily be computed. Venoclysis of dextrose solution, if prolonged for hours or days in a patient who particularly needs this on account of various chronic states or dehydration, must be given much more slowly than single doses in order to avoid pancreatic stimulation and overproduction of endogenous insulin with hypoglycemic reactions and shock in the actual presence of an intravenous injection of dextrose, if such a paradoxical fact can be accepted. On this account the concentration of the dextrose solution must be reduced for venoclysis to 5, or at the most 10 per cent, while the flow rate must also be slowed down, like that of the hypertonic solutions, to not more than 4 or 5 cc. per minute, in order to avoid this overstimulation of the pancreas, whereupon venoclysis may be prolonged indefinitely to the great benefit of the patient.

DR. ROBERT KAPISNOW, Lafayette, La. The intravenous drip is indicated in every condition that results in a blood concentration. This includes the entire field of anhydremia. The mechanism of anhydremia may be divided into three groups: those due to simple water deprivation; those due to excessive fluid lost either through profuse vomiting, sweating or diarrhea, and, lastly, those conditions produced by a loss of fluid from the blood stream due to increased capillary permeability. In the first group, including such conditions as water deprivation on the desert for example, or as found in the mentally deranged patients are quickly restored by the administration of relatively small amounts of fluid introduced through any channel. In the second group are cases of profuse sweating in deep mines or in boiler rooms. Large volumes of fluid

containing sodium and chlorine ions are lost in the profuse vomiting of pregnancy, high intestinal obstruction in adults and pyloric obstruction in infants. Numerous drugs likewise incite pernicious vomiting. Various gastric and intestinal fistulas rapidly lead to depletion of the water storage of the body. The severe diarrheas of cholera or the bacillary types of dysentery, colitis of the ulcerative or tuberculous type, the diarrheas of infancy or the excessive use of purgatives may account for the loss of many liters of fluid daily. This group requires more than the simple administration of plain water. Either sodium chloride or dextrose must be administered. In this group, any method of introduction of fluids will avail. In the third group, resulting in anhydremia due to loss of fluid from increased capillary permeability, the intravenous drip is the most important. These are gas poisoning, influenza, extensive superficial burns, eclampsia, severe urticarial phenomena, acute medical shock or histamine or peptone shock.

DR. HAROLD T. HYMAN, New York. Dr Titus's criticism of our title is just. We use the term "intravenous drip" or "slow intravenous drip" in order to emphasize to the clinicians the necessity of doing this procedure slowly. In our own institution, and despite everything we may say, we find, in a crisis, that the interns become alarmed and turn the drip on as rapidly as possible. Concerning Dr Orr's warning about reactions, I wish to emphasize that I think that it is only fair, though, to point out that one cannot compare conditions in a rabbit weighing 4 or 5 Kg and those in a normal individual weighing 50 or 60 Kg. One cannot give a continuous slow intravenous drip in a rabbit at a rate comparable to 2 cc a minute without that drip stopping up. If it does run, it means that the rabbit is getting comparatively more fluid, and under those circumstances there will be edema of the lungs and emboli. In our clinical experience, even in two fatal cases, we did not find pulmonary emboli. If pulmonary emboli occur, it is probably due to a technical error comparable to what we call speed shock.

THE METABOLISM OF LEVULOSE

VI THE INFLUENCE OF THE LEVEL OF OVARIAN FUNCTION

ALLAN WINTER ROWE, PH D

MARY A McMANUS, AB

AND

ALBERT J PLUMMER, AM

BOSTON

Earlier communications on the levulose tolerance have dealt severally with certain general conditions¹ and with the influence of hepatic dysfunction² and of pregnancy³. The present paper is a complement to the last of the foregoing and deals with the influence of the level of ovarian activity. Previous studies in this field in which galactose was the test sugar⁴ had demonstrated a very marked effect of the age and sexual status on the amount of the latter sugar susceptible of utilization by the organism. In the present instance, similar series have been studied, levulose of the highest purity being used, a necessary precaution,¹ for purposes of control the galactose tolerance has also been

determined. The general method of approach has already been discussed,¹ it may be enough here to state that each subject was given a thorough general clinical and laboratory survey, which included as a routine a careful physical examination, the compilation of an exhaustive medical history, analyses of the blood and urine, measurement of the respiratory metabolism,

TABLE 1—Composition of Groups

Group	No. of Cases	Age Range	Average Age
Prepubescent	13	5-13 years	10 years
Pubescent	11	11-14 years	13 years
Adult	22	18-26 years	20 years
Castrate	15	21-51 years	34 years
Castrate with endocrine complementation	4	22-60 years	37 years

and a variety of other tests and observations among which were a cardiogram, an audiogram, a radiologic study and a neurologic examination.⁵ As in the earlier studies, the Hofmeister⁶ technique, the administration of successive graded doses, was followed, an exceeded tolerance was indicated by the appearance of detectable amounts of levulose in the urine. A positive qualitative test was followed by a quantitative study, the Benedict⁸ and Folin-Berglund⁹ methods being supplemented by fermentation with washed yeast and by the polariscope. The complete analytic approach will be discussed in a forthcoming paper shortly. Earlier studies¹ have demonstrated the limitation of

the approach by the blood sugar curve method, particularly when levulose, with its slight influence on blood sugar levels, is the test sugar. While 10 Gm differences were selected for the galactose program, the recognized higher tolerance of the organism led to the adoption of the larger interval of 25 Gm for grading the levulose dosage. The general program can be shown most compactly in chart 1.

Modifications of this general scheme were easily applied to special cases, thus effecting a saving in time and in the costly sugar used for the study. The basic data of the several groups falling in this series are collected in table 1. Additional details are given in the discussion of the results with each of the several groups. The recognition of departures from the normal presupposes a definition of the latter quantity. As else-

where noted,¹ there are but limited reports of normal studies in the literature, and the results recorded show a serious lack of concordance. The use of so-called hospital normals as test subjects and failure to make due allowance for the carbohydrate paradox (Allen) are unquestionably principal factors in producing this lack of agreement. A few data drawn from the literature serve to illustrate the conflicting evidence. The earliest papers derive from the studies produced by Strauss's¹⁰ initial proposal to use levulose tolerance as a test for liver function, the two latest, the reawakened interest in the potentialities of this sugar for function testing.

Turning to the first study group, we have a series of thirteen normal children ranging in age from 5 to 13 years, none of whom had established the catamenia or indeed gave somatic evidence of an imminent approach of maturation. They were hospitalized during the study, and the more elaborate and detailed approach

TABLE 3—Prepuberal

Datum	Variation	Average

Galactose tolerance	20 Gm.	20 Gm.
Levulose tolerance	75 Gm. to 100 Gm.	81 Gm.

designated as the "long form"⁵ was utilized for the investigation of each case.

All these children had been previously institutionalized¹¹ to correct very poor social backgrounds, and the prevailing underweight of the group reflects these unfortunate earlier conditions. They were being most adequately provided for at the time of the transfer for this study, however, and as a further safeguard were given several days of liberal feeding¹² before the sugar testing was initiated. The basal rate levels were probably influenced by an earlier protein inadequacy associated with their undernutrition, although but one (-17 per cent) exceeded the conventional low limit of the normal. The prevailing level of alveolar carbon dioxide tensions was somewhat low throughout the group, and such levels we have found to be a rather common observation in similar groups of children. There is no evidence of an acidosis, it is possibly refer-

Chart 1—Levulose program: additional doses at appropriate levels when first three days fail to give positive test.

able to their sexual status, but the question is one falling outside the present discussion. Blood sugars are normal, the galactose tolerance was uniformly at the level that the earlier studies have shown to be that of normal prediction. The levulose tolerance, i.e., initial positive response, was at either 75 or 100 Gm, the first

predominating, as could be inferred from the reported average. The child organism is apparently able to utilize some four times as much of this hexose as of galactose.

The children in the next group (table 4) ranged from those who had just matured to those who had been menstruating for a number of months but all less

TABLE 4—*Pubescent*

Levulose tolerance	75 Gm to 100 Gm	89 Gm

than one year. They were drawn from the same institution as the prepubescent children and the same conditions influencing weight had been operative with them. They too were hospitalized and had been given several days of preliminary feeding before the sugar tests were begun. Several of them had basal rates below the conventional limit of -10 per cent, the same earlier condition of a partial protein inanition obtained even more definitely in this group, as from their age they had been longer subjected to subversive nutritional influences. The one patient with marked lowering (-25 per cent) gave no evidence of other physical abnormality than that of underweight (-14 per cent). A thyroid failure could not be excluded in this single instance but, as this condition would have but little if any influence on the sugar tolerance, inclusion of the

TABLE 5—*Young Adult*

Datum	Variation	Average
Weight deviation	+40% to -16%	-2%
Basal rate deviation	+6% to -10%	-6%
Alveolar carbon dioxide	39 mm to 47 mm	41 mm
Blood sugar	80 mg to 95 mg	87 mg
Galactose tolerance	40 Gm	49 Gm
Levulose tolerance	100 Gm to 125 Gm	105 Gm

case is felt to be warranted. The low alveolar carbon dioxide has already received comment with the preceding group.

The galactose tolerance ranged from the prepuberal to the adult tolerance with rough correlation between sugar level and duration of the catamena. Previous studies⁴ already cited have shown that the adult level of 40 Gm is usually attained by the end of the first year or shortly thereafter.

The levulose tolerance shows the same range as with the preceding younger group, but the average is higher, the 100 Gm doses being more frequently encountered. In other words, levulose tolerance shows the same upward trend as does galactose, but in a much less marked degree and seemingly at a slower rate of change.

The group of young women¹³ in table 5 were drawn from several sources, chiefly from the students in two women's colleges and a nurses' training school. They were studied initially under the program of the abridged type ("short form"),⁵ supplemented by such tests and observations as the apparent needs of the individual case required. The one obese girl (+40 per cent) had a somewhat low sitting height index, so that the expression of her overweight is somewhat too high

She was a large framed powerful girl living an actively athletic life, her overweight was seemingly no more than a personal characteristic. Only two of the basal rates were significantly below conventional normal standards (-16 per cent, and -19 per cent), and in both a dietary tribute to current mores was probably the background, as both had low urine nitrogen elimination. They made the sacrifice however of an ample carbohydrate intake for several days before the sugar testing. The carbon dioxide tensions and blood sugar levels are normal both as to average and as to the individual measurements. The galactose tolerance was at the 40 Gm level, which past experience has indicated to be the norm for the premenopausal female adult. Levulose tolerances likewise show a continuance of the upward trend manifested in the pubescent group, with 100 Gm the common result but a sufficient number at 125 Gm to exercise a modest effect on the average. We believe that both must be regarded as normal but

TABLE 6—*Castrates Recent Two to Three Weeks*

that the lower level of 100 Gm will be more frequently encountered among the normal, healthy adult group. While the averages for the three groups already discussed show an unmistakable upward trend, there is lacking among them those relatively sharp lines of demarcation which mark the progressive stadia of the galactose tolerance.

As has been noted in several of our previous papers, there is reason to conceive of a special influence of the mammary glands on the metabolism of galactose. Certainly both synthesis and storage of this sugar are implicit in lactation, and we have reported two small series of cases¹⁴ in which patients after bilateral mastectomy, in which malignant neoplasm was ruled out, showed a decline of the galactose tolerance to the characteristic prepuberal level of 20 Gm. Levulose would not enter into any such selective mechanism and the

† Low protein later record -10 per cent

present data offer some further support to the general hypothesis. In the second paper cited,³ removal of the breasts produced no significant change in the response to levulose.

Whatever may be the true explanation, it must be recognized that while changes in the levulose tolerance show a rough qualitative agreement with those of galactose, quantitatively they are less significant and less sharply defined.

¹³ The authors are indebted to all who participated in these studies in the case of the patients at no small inconvenience to themselves.

Turning to pathologic material for an extension of the present thesis, the results of castration may next be considered. In dealing with individuals presenting this condition, however, extreme caution is needed in the interpretation of results. Residua of the influences which initially led to the operation may in themselves modify the sugar metabolism and the presence of significant and possibly independent complications arising

at a later date must not be overlooked. For this reason the standardizing studies were made as comprehensive as possible, even with this precaution the need for conservatism in interpretation remains.

The patients in this group (table 6) were examined immediately at the end of their convalescence following castration. Cystic ovaries and inflammatory pelvic conditions—in two instances only of a possibly specific origin—were the basis of the surgical intervention. The weight fluctuations reflect the status of the individual subject, some of whom were undoubtedly cases of functional hypogonadism prior to the operative confirmation of their endocrine status. The basal rates all show a downward tendency, the well known difficulty of securing basality in the case of ovarian failure is emphasized in this group with the added factor of the disturbance of a recent major operation. The carbon dioxide values are transitional and the blood sugars normal as was to be anticipated. The galactose tolerance shows fluctuations both above and below the anticipated terminal level, though the average closely approximates it. The results with levulose practically duplicate those with the galactose, although no one test was inferior to the lower level observed in prepubescence. The average, 86 Gm, approximates that of the latter group.

The second group of castrates (table 7) is composed of a group of women whose ablating operation had taken place from one to eleven years prior to the time of study. With this group the establishment of compensatory adjustments and the development of later complicating and unassociated conditions are both factors to be borne in mind in evaluating the results. Broadly the general data reflect the underlying condition. The tendency to obesity is more pronounced, the basal rate levels are more representative. The carbon dioxide tensions in the relatively normal average reflect a possible compensatory mechanism. The galactose tolerance is at the anticipated prepuberal level, an evidence of the probable absence of disturbing factors that might affect the metabolism of this sugar.

On the other hand, the levulose values show a very wide scatter from a point well below the normal low prepuberal tolerance to one superior to that of the normal adult. With so small a series as the present, a single extreme value exercises an undue influence on any average. For example deleting the single high

value (150 Gm) lowers the average to 85 Gm, while if both of the extreme cases are omitted the average is at the wholly normal level of 100 Gm. Careful study of these individual cases failed to disclose any known reason for their profoundly altered levulose metabolism. The values can only be given as they stand with just recognition of the limitations imposed by so small a group.

One last small group may be added in which an ovarian failure of surgical origin is complicated by a known endocrinopathy involving another focus. Each case must be recorded separately, as there is lacking the necessary parity for collective presentation.

Patients 1 and 2 were castrates of sixteen and fifteen years' standing respectively, with a current hypothyroidism. In addition, in case 1 both breasts had been removed some two years previously for a non malignant condition. They both presented manifestations characteristic of the active thyroid status, the galactose tolerance was depressed to a 10 Gm level, the levulose figures, on the other hand, were those of normal intact adults. Seven other cases of uncomplicated hyperthyroidism ranged from 25 to 125 Gm with an average of 92 Gm (unpublished data), the depressing effect of this condition on the galactose tolerance has been noted in several of our earlier papers. Patient 3 had been successfully operated on for a toxic thyroid some twenty years earlier, and four years later the ovaries had been removed. The normal basal rate may be a reflection of an algebraic compensation between a residual upward influence of the remaining thyroid tissue and the depression from the castration. The galactose level at 10 Gm offers modest support for this interpretation. The levulose tolerance is again that of the normal adult.

Finally, case 4 was one of mild diabetes in which castration had been done four years previously. The galactose level is consistent with this double depressing influence and here the levulose result is equally responsive to the pancreatic action. So low a level, however,

Chart 2—Solid line level of galactose tolerance broken line level of levulose tolerance

is not to be regarded as characteristic, as a small group of patients with uncomplicated diabetes gave an average of 73 Gm for their levulose tolerance (unpublished data).

COMMENT

In view of the running comment on each series, but little additional discussion is needed. Obviously the mechanisms of utilization of the two sugars are not identical, although both respond to certain agencies in kind though not in degree. The level of ovarian

activity, so potent in determining either directly or indirectly the utilization of galactose, is but qualitatively reflected in the changing levels of levulose metabolism. Castration produces a wide scatter in the levulose results, some of which are presumably mediated by agencies at present unknown and seemingly not operative in the metabolism of galactose. A clear-cut thyroid effect on levulose is not significantly indicated in the few available results.

With recognition of its limitations, the fluctuations of the two sugar tolerances may be diagrammatically presented (chart 2)

ABSTRACT OF DISCUSSION

DR HENRY J JOHN, Cleveland This work presents an interesting problem, apparently new, the effect of the gonads on the metabolism of levulose. I found something of that sort in my studies of the dextrose tolerance work in the various endocrine groups, gonadal and otherwise. The metabolism of levulose was once considered to be largely a liver function. Here it is being found that there are other things which are affecting it and changing the picture. Extreme care must be used with regard to what is called a normal standard, a normal individual. If one goes over a small series of any type of test one gets a certain impression. After one has multiplied that series 100 or 1,000 times the picture usually changes extremely, sometimes one has just the opposite impression. The final word here, of course, will be said when the work has progressed still further and when more has been learned about the endocrine end of it as it affects the metabolism of levulose.

ALLERGY TO CHICLE

PRELIMINARY REPORT

A I KLEINMAN, M.D.
BROOKLYN

My object in this paper is to report the occurrence of allergic manifestations following the use of chewing gum. There has been no similar report, to my knowledge, in the literature.

CASE 1—A. S., a white school boy, aged 16, seen in October 1933 complained that whenever he chewed gum he experienced attacks of sneezing, itching and swelling of the eyes, and occasionally spasmodic coughing. These symptoms generally set in within one half to three quarters of an hour after the gum was first taken and subsided about two hours after its removal. Subsequently he observed that, if he chewed gum more rapidly, the onset of the symptoms was accelerated.

The past history was that of the usual childhood diseases. There was no history of symptoms of the upper respiratory tract. The tonsils had been removed some years before. With the exception of the present complaint there was no previous history of any form of allergy or drug idiosyncrasy. His younger brother is under treatment for ragweed hay fever and food asthma, and his mother is subject to migraine.

The boy was well developed and nourished, was 5 feet 7 inches (170 cm) in height and weighed 135 pounds (61 Kg). The eyes were normal and the conjunctivae clear. There was no obstruction of the nasal passages, and the nasal mucous membrane appeared normal. There was evidence of tonsillectomy. Examination of the thorax showed the heart and lungs to be within normal limits. The blood pressure was 110 systolic and 80 diastolic. No abnormalities were noted.

In order to establish which constituent of chewing gum caused the allergic symptoms, its several ingredients were used in testing. Intradermal tests with milk and corn meal were negative. A drop of oil of peppermint (he was partial to this flavor), placed on the tongue did not result in any reaction. He was tested for salicylates because oil of wintergreen which contains from 98 to 99 per cent of methyl salicylate is used

as a flavoring in some chewing gum. Acetylsalicylic acid was used for this test by having the patient ingest a five grain tablet and also by the method suggested by Duke.¹ The latter consists of placing several small specks of a tablet on the patient's tongue and allowing the alkaline juices of the saliva to break up the acetylsalicylic acid into sodium salicylate and sodium acetate. The reaction, if any, should occur within one minute. No reaction either immediate or delayed occurred in either instance.

The final substance to be investigated was chicle, and the boy was therefore tested with various extracts of both refined and crude chicle.² Three minutes after the introduction of concentrated chicle extract intradermally the patient commenced to sneeze, the spasms were progressively more violent, the conjunctivae became congested and he complained of severe itching of the eyes and was restless and irritable. Dyspnea and spasmodic coughing became evident and later edema of the eyelids was observed to be setting in. Locally, the sites of the intradermal tests showed wheals measuring 7 by 3 cm in diameter with marked pseudopods. The reaction to the crude and refined chicle extracts appeared to be identical. Because of the severity of the reactions, weaker extracts (4 per cent) were then prepared and on a subsequent occasion the boy was retested with them. At this time the chronological sequence of the symptoms was carefully observed. Five minutes following the tests with the dilute extracts the boy complained of dizziness, which was followed in four minutes by itching of the eyes and sneezing. The latter symptoms, which came on about the same time, became progressively more severe in character. Fifteen minutes after the tests were introduced asthmatic breathing was noted, and twenty minutes afterward edema of the left lower eyelid. The latter became more marked gradually, involving also the upper lid. The wheals that occurred at the sites of the tests reached their maximum dimensions in fifteen minutes and exhibited marked pseudopodic processes. The most marked local reaction occurred from chicle that had been freed from the acetone-soluble fraction and dissolved in Coca's solution. The patient complained of marked itching of the arm around the wheals.

On both occasions, inspection by a nasal speculum revealed the mucous membrane of the nose to be edematous and the turbinates turgescant. The conjunctivae were also congested. On auscultation of the chest, sibilant and sonorous rales were heard. One cc. of epinephrine was required to control the severe symptoms following the use of the concentrated extracts, and 0.3 cc. when the dilute preparation was used. Ephedrine in combination with a sedative was prescribed to be taken at home, on account of the marked systemic reaction. The edema of the eyelids was the last symptom to disappear in both instances.

CASE 2—M. R., a white man, aged 29, a dentist, seen, March 23, 1934 complained of a clogged nose, rhinorrhea ever since he could remember, and sneezing attacks with general aggravation of symptoms since December 1933. The rhinorrhea and sneezing were of such a severe character as to inconvenience him seriously and embarrass him in the practice of his profession. No antecedent family history was elicited, but his son aged 3 years, had manifested urticarial eruptions on several occasions. The personal history was that of frequent "colds" all the year round as long as he could remember.

The patient had a mild tendency to obesity was 5 feet 7½ inches (171 cm) in height and weighed 168 pounds (76 Kg). The nose was obstructed, the turbinates were markedly turgescant, especially on the right side, the septum was deviated and the mucous membrane was pale and boggy in appearance. The tonsils were out and there was no postnasal discharge. The heart showed no evident enlargement. The sounds were somewhat distant. The blood pressure was 110 systolic and 84 diastolic. The lungs were clear at the time of the examination and other physical manifestations within normal limits.

¹ Duke, W. W. Aspirin Allergy. A Method of Testing Aspirin Sensitiveness and a Method of Avoiding Aspirin Catastrophes, J. Allergy 5: 426 (July) 1933.

² The chicle used was obtained from the three main manufacturers of chewing gum in the United States. Two types of extracts were prepared for testing: one was crude or refined chicle in Coca's solution or distilled water; in the other type the chicle was first subjected to extraction with acetone, and the acetone-insoluble residue was extracted with Coca's solution or distilled water.

Intradermal tests were performed with the usual inhalants and foods. Orris root, 0.001 mg of nitrogen per cubic centimeter of extract as determined with the Kjeldahl method, when introduced intradermally, resulted in a tremendous wheal about 6 by 4 cm in diameter with pseudopods. Violent sneezing and rhinorrhea set in about three minutes after the test was introduced. Epinephrine was required to control the symptoms. Marked reactions were also obtained to some vegetables and fruits and also to timothy, but without systemic reactions.

Intradermal tests with extracts of chicle on another occasion resulted in very marked wheals similar to those in case 1 and approximating the patient's orris root reaction, including the nasal and asthmatic symptoms. Clinically it was difficult for him to note any effects from chewing gum as he had been having nasal symptoms almost continuously.

Twenty-five other cases of allergic individuals, mostly cases of seasonal hay fever, and six nonallergic arthritic patients were tested with the concentrated extracts of chicle. Only one case exhibited a moderately positive local skin reaction, but no confirmatory clinical history was elicited.

Ordinary chewing gum has as its base chicle gum, into which are incorporated sugar, corn syrup and flavoring oils. The most common of the latter are wintergreen, peppermint and spearmint. One brand of chewing gum contains also milk. The formula varies with the manufacturer, but the base used in most cases is one or another variety of chicle.

Allergy to chicle is of interest because of its widespread use in the manufacture of chewing gum and medicated gums.

Chicle is the solidified latex or sap of one or more varieties of the species of the genus *Achras* trees.³ The latter are native to Central and South American countries, notably southern Mexico, British Honduras and Guatemala. *Achras zapota*, a plant common in all tropical countries, is stated to be the source for the best grades of chicle. Most of the chicle imported into the United States comes from Mexico.

Chemically, chicle is a mixture of water-soluble gum, resins, gutta and mineral constituents. The composition, according to Dannerth,⁴ is given in the accompanying table.

The chemical nature of the substance in chicle which produced the symptoms cited in our case is at present being investigated.

Composition of Chicle

	Per Cent
Resin (acetone soluble)	40
Gutta and carbohydrates	17.4
Proteins	0.6
Water	3.0
Ash	4.7
Foreign matter	2.3

Before the crude chicle is used in the manufacture of chewing gum, according to Roberts,⁵ it is washed and dried in separate chambers to reduce the moisture to approximately 4 to 6 per cent. The chicle is then heated until it flows freely and allowed to pass filters under 200 pounds of pressure to remove the fibrinous material. The purified gum is now passed into mixing kettles, where the sugar and flavoring oils are incor-

porated. Specialized automatic machines are used in producing from this mixture the final product ready for market.

SUMMARY

Two cases exhibited marked positive local skin reactions when tested intradermally with extracts of chicle. In one case (case 1) Cooke's postulates⁷ were satisfied. These require (1) that there should be a positive skin reaction with the suspected substance, (2) a history of exposure to the substance in question, and (3) the ability to reproduce the symptoms when the patient is exposed to it. The other case (case 2) presented obvious difficulties in establishing a positive clinical history. The marked positive skin tests, however, associated with systemic reactions, leads one to suspect strongly that this patient also had genuine chicle allergy.

It was also proved that chicle does not act as a skin irritant producing nonspecific reactions by the fact that out of twenty-five allergic patients only one showed a moderately positive skin reaction.

A SUCCESSFUL METHOD FOR VACCINATION AGAINST ACUTE ANTERIOR POLIOMYELITIS

FURTHER REPORT

JOHN A. KOLMER, MD, LL.D., Sc.D.

Professor of Medicine, Temple University School of Medicine and
Director of the Research Institute of Cutaneous Medicine

WITH THE ASSISTANCE OF

GEORGE F. KLUGH, JR., MD

Resident in Medicine, Temple University Hospital

AND

MISS ANNA M. RULE

PHILADELPHIA

As recently stated by Kolmer and Rule,¹ it is possible to vaccinate *Macacus rhesus* monkeys safely and successfully against acute anterior poliomyelitis with subcutaneous and intracutaneous injections of vaccines of living but attenuated virus composed of 4 per cent suspensions of poliomyelitic monkey spinal cord in sterile 1 per cent solutions of sodium ricinoleate. All of a series of eighteen monkeys were immunized sufficiently without the slightest evidences of ill effects to protect them completely against infection following the intracerebral injection of about eighteen minimal infective doses of virus given under ether anesthesia about one month after the last dose of vaccine, the disease developing in unvaccinated controls in from five to nine days after inoculation.

Following these observations, two of us received subcutaneous injections of 0.5, 1.5 and 2 cc. of the vaccine at intervals of five days without any ill effects whatever except local reactions at the sites of injection, and two weeks later our serums were found to contain large amounts of antibody in neutralization tests.

During the previous year, Kolmer and Rule succeeded in vaccinating one monkey partially and two

⁶ The exact meaning of the word washed could not be determined by the writer either from the literature or by communication with manufacturers. One manufacturer writes: The washings of some chicles entail the use of some agents which are used for the removal of some of the resins.

additional animals completely, out of a series of six, with subcutaneous and intracutaneous injections of a vaccine of 2 per cent poliomyelitic spinal cord in 10 per cent sodium ricinoleate, so that the latter or stronger vaccine yielded much more satisfactory results with milder local reactions at the sites of injection, owing to the lower concentration of sodium ricinoleate.

Owing to the fact that it appears that living vaccines of attenuated viruses are more vaccinogenic than heat or chemically killed viruses we employed sodium ricinoleate (William Merrell Company *) as the attenuating agent not only because it is known to be detoxifying,³ but likewise because McKinley and Larson⁴ had successfully immunized three monkeys completely and one partially with intraperitoneal injections of sodium ricinoleate treated emulsions of monkey spinal cord virus. At least it would appear that vaccines of attenuated viruses produce immunity in much smaller amounts than "dead" viruses, with the added advantage that the viruses after injection are probably able to multiply many fold with continued antigenic stimulation as well as requiring the injection of smaller amounts of spinal cord protein and thereby resulting in less strain on the antibody producing tissues and less likelihood of producing allergic sensitization.

Furthermore, marked success in the case of poliomyelitis has followed vaccination of monkeys with subcutaneous and intracutaneous injections of living virus or mixtures of virus and immune serum,⁵ but these have been considered too dangerous for the vaccination of human beings.

Susceptibility, attack rate, mortality and incidence of residual paralysis and other factors in acute poliomyelitis in relation to vaccination of human beings have been discussed elsewhere,⁶ it being pointed out that susceptibility is so high in children and especially among those under 10 years of age that a safe and effective method of vaccination is highly desirable and especially in epidemics, although the majority of adults appear to possess adequate resistance. Even among the latter, however, vaccination is worthy of serious consideration during epidemics at least since serum neutralization tests by different investigators with a group of 128 varying in age from 15 years and upward has shown about 24.7 per cent without demonstrable amounts of neutralizing antibody in the blood.

METHOD OF STUDY

During the last four months we have administered the vaccine to a selected group of twenty-five children varying in age from 8 months to 15 years, as summarized in the table, with completely negative histories of clinical attacks of poliomyelitis. All were immunized at the request or with the written consent of the parents, nineteen being in Temple University Hospital in the pediatric service of Dr Ralph M. Tyson, to whom we are indebted for this cooperation. While all these children were in fairly good health, the majority were convalescing from various medical and surgical ailments.

Fifteen of these children were selected on the basis of showing no antibody in the blood by serum neutralization tests and ten with antibody in order to include both types in the study. These tests were conducted by mixing 0.5 cc of serum with 0.5 cc of a 10 per cent suspension of virus followed by intracerebral injection of 0.5 cc of each mixture into monkeys under ether anesthesia after being allowed to stand about two hours in a water bath at 37 C. Control monkeys injected with 0.5 cc of a mixture of 0.5 cc of sterile saline solution and 0.5 cc of virus after standing under identical conditions developed paralysis in from five to nine days.

Temperature observations and blood examinations were made in twenty-two of the children before and after each dose of vaccine.

From one to three injections were given subcutaneously at weekly intervals, the amounts of each being shown in the table.

RESULTS OF VACCINATION

There were no ill effects in any of the children, and not the slightest evidences of infection. Local reactions of varying degree occurred at the sites of infection. In one of the older children the first dose produced a moderately severe reaction of swelling and erythema corresponding to that sometimes seen following injections of diphtheria toxoid but in the remainder the local reactions were of mild degree.

During the first twenty-four hours after injection and especially after the first, the temperature of some of the children was elevated to a fraction of a degree but only occasionally going as high as 100.2 F and falling to the preinjection levels in about forty-eight hours.

The total leukocytes were increased from 500 to 1,200 per cubic millimeter of blood in some of the children during twenty-four hours following injections and especially after the first, as the result of a slight absolute increase of the polymorphonuclear neutrophils. These and the slight temperature changes were

ascribed to the effects of the local reactions, as they appeared to vary with the degree of the latter

Serum neutralization tests for antibody were conducted one week after the last dose of vaccine by mixing 0.5 cc of serum with 0.5 cc of a 10 per cent suspension of virus, allowing it to stand at 37 C for but one to two hours, and injecting 0.5 cc of each mixture intracerebrally into monkeys under ether anesthesia

In the fifteen children without antibody before immunization, eleven or 75 per cent, showed sufficient amounts of antibody to neutralize the virus after immunization, the monkeys showing absolutely no evidences of infection over three to four weeks following intracerebral inoculation of the serum-virus mixtures, while the controls inoculated with but 0.1 cc of virus alone became paralyzed in from six to nine days and succumbed

Since Brodie⁷ has recently shown that the maximum immunity from two intracutaneous doses of poliomyelitis virus in monkeys is obtained by giving the second while the first is giving its effects in other words at intervals of from ten to fourteen days apart, it is quite likely that our injections at weekly intervals were too closely spaced and that even better results might have been produced by giving the injections at longer intervals. Furthermore, while antibody production in some of the children appeared to be quite prompt after injections of the vaccine, as will be discussed shortly in more detail it is likely that serum neutralization tests for antibody should be delayed for at least two weeks after the last dose instead of but one week as conducted by us

In addition it should be stated as previously mentioned that the majority of children included in this group were convalescing in the hospital from various medical and surgical conditions with the possibility that antibody response may not be as good under the circumstances as occurs in children in excellent general health

Despite these conditions, however, the production of large amounts of antibody in eleven out of fifteen, or 75 per cent, of susceptible antibody-free children by from one to three doses of vaccine, with absolutely no ill effects other than the slight local reactions at the sites of subcutaneous injection, indicates a satisfactory and successful degree of immunization

Furthermore, the serums of the ten children containing antiviral antibody in the blood before vaccination showed a sharp increase of antibody after immunization, since 0.5 cc of serum mixed with as much as 0.5 cc of 50 per cent suspension of virus followed by the intracerebral injection into monkeys under ether anesthesia of 0.5 cc of the mixtures, after standing but one to two hours at 37 C, showed complete neutralization. Indeed, it would appear from additional quantitative tests that the vaccine probably produces more antibody in those children carrying natural antibody in the blood than it does in those who do not, suggesting that the body cells in the former are probably sensitized or "tuned up" by previous unrecognized infection with virus, with the result that they produce large additional amounts of antibody on additional stimulation by vaccine. At least twenty-one, or 84 per cent of the group of twenty-five children, showed good antibody response to the vaccine

DOSAGE OF VACCINE

The matter of dosage is of course one of considerable importance. Monkeys receiving a total of 0.5 cc. per kilogram in divided doses by subcutaneous injection have been successfully vaccinated,¹ but, if it is true that human beings acquire immunity to poliomyelitis by clinically unrecognized infection with virus, it would appear that less vaccine may be required per body weight for effective immunization than in the case of monkeys

With this possibility in mind and as an additional factor of safety, we have made the first dose 0.25 cc. for children under 3 years of age and 0.5 cc for older children and adults. Second doses have varied from 0.5 to 1 cc and third doses 1 or 2 cc, as shown in the table

From the results observed up to the present time, it would appear that three doses are sufficient in the following amounts

From 1 to 3 years	first 0.25 cc., second 0.5 cc., third, 0.5 cc.
From 4 to 10 years	first 0.5 cc., second 0.5 cc., third, 1 cc.
From 11 to 15 years	first, 0.5 cc. second, 1 cc., third, 1 or 2 cc.
Adults	first, 0.5 cc., second, 1 cc., third, 2 cc.

For children of standard weight the totals of these amounts of vaccine varied from about 0.06 to 0.1 cc. per kilogram, which were therefore approximately five to ten times less per body weight than given to monkeys. But we have assumed, as stated before, that human beings may require less than monkeys per kilogram of weight and the results summarized in the table appear to substantiate this assumption. A possible exception was in the case of the two children (1 and 4) of 8 and 12 months respectively, who probably should have received 1 cc for the third dose instead of 0.5 cc, but otherwise we believe that the foregoing scale is about right in view of our present information on this subject

However, it would appear that but one or two doses of vaccine have produced considerable antibody in at least some of the children

For example, the serums of Nicholas V (patient 2) aged 9 months, and Howard N (patient 5) aged 19 months, gave good neutralization tests four days after one dose of 0.5 cc. Joseph W (patient 4), aged 12 months, gave a good neutralization test one week after the second dose, although this result was not known when the third dose was given, and Clinton B (patient 19), aged 8 years, also gave a good neutralization test four days after the first dose of 0.5 cc., although the second and third doses were also given before this result was known. These results indicate that with some children at least one or two doses may suffice, but since Raymond B (patient 1), Phillip B (patient 3) and Francis B (patient 6) did not show antibody in the serums one week after the first dose, we believe it is advisable to give two and preferably three doses of the vaccine

RAPIDITY OF ANTIBODY PRODUCTION AND SPACING OF INJECTIONS

In view, however, of Dr Brodie's observations previously referred to on the rate of production of antibody in monkeys given subinfective doses of living virus intracutaneously, it would appear advisable to give the injections every ten days instead of every seven days as we gave them

On the other hand, we have observed rather rapid antibody production in the cases just referred to,

namely, Nickolas V (patient 2), Howard N (patient 5) and Clinton B (patient 19), since their serums taken ninety-six hours after the first dose of vaccine gave good neutralization tests. Indeed, in the case of Nickolas V, serum taken forty-eight hours after the first dose of vaccine appeared to contain already a very slight amount of antibody, as this monkey did not develop paralysis until eighteen days after intracerebral inoculation, whereas the control monkey and that tested with serum before vaccine was given developed severe paralysis thirteen or fourteen days after inoculation.

Further evidence of rather rapid antibody production was indicated by the fact that a monkey weighing 4 Kg injected intracerebrally under ether anesthesia with 0.5 cc of 5 per cent virus seventy-two hours after a subcutaneous injection of 0.5 cc of vaccine remained perfectly well and entirely free of infection, whereas a control developed paralysis eight days after inoculation with but 0.1 cc of the same virus given at the same time. In the case of a second monkey, however, receiving the same dose of vaccine the antibody response, while present, was not quite as good, as this animal developed paralysis about nineteen days after the intracerebral injection under ether anesthesia of 0.5 cc of the 5 per cent virus.

In this connection, observations on the rapidity of antibody production with the serums of individuals and monkeys with poliomyelitis are not without interest and some bearing on this question. Flexner and Amoss,⁸ for example, have found antibody in the serum as early as the sixth day of the disease. Amoss⁹ has found it in monkeys as early as three and one-half days after the onset of paralysis and in human beings as early as the fifth day. Leiner and von Wiesner¹⁰ found it after seven, and in one case two days after the development of active disease in monkeys. Brodie¹¹ also found antibody in the blood of monkeys on the second day after the height of paralysis, while Howitt¹² failed to find it earlier than fifteen days after the onset of the disease in monkeys.

On the whole, therefore it would appear that antibody may be produced rather rapidly in poliomyelitis and after subcutaneous injections of the vaccine and for this reason we believe that vaccination may prove particularly helpful in the immunization of individuals during epidemics. Furthermore, as has been discussed elsewhere,⁶ it does not appear that the vaccine produces a detectable "negative phase" or period of increased susceptibility in monkeys at least, which also appears to justify its use in combating epidemics of poliomyelitis.

THE VACCINE

The method of preparing the vaccine has already been described¹ and need not be here given. Suffice it to emphasize that it is prepared of a remote monkey passage strain of the virus with the possibility of having lost at least some of its infectivity for human beings. That the antibody it produces is capable of neutralizing human virus⁶ is indicated by the fact that the antibody in the serums of several of the vaccinated children was found to neutralize completely human virus from the 1934 epidemic in California sent us by Dr Jessel of Los Angeles and a second virus in the third monkey transfer sent by Miss Howitt of San Francisco.

The vaccine however, cannot be prepared of brain tissue because it contains insufficient virus. The intracerebral inoculation of monkeys with as much as 1 cc of a 50 per cent suspension of fresh brain has failed to infect because virus was absent or present in insufficient amounts. But the spinal cord of one monkey will furnish about 150 cc of vaccine, which is sufficient for the immunization of from forty to seventy-five children depending on age and dosage.

We believe that the virus in the vaccine is attenuated to some extent by the amounts of sodium ricinoleate employed. While the intracerebral injection into monkeys under ether anesthesia of 0.1 cc of 5 per cent fresh virus produced poliomyelitis in about eight days, the intracerebral injection of 0.2 cc of a vaccine 3 weeks old and carrying 4 per cent of virus produced poliomyelitis in eleven days, while a second vaccine 2 months old produced paralysis in nine days and a third about 5 months old in about twelve days all being injected in doses of 0.2 cc under ether anesthesia.

The vaccine is allowed to stand at least two weeks before use and we now believe that a month may be better. After this time attenuation of the vaccine appears to stop when kept in the refrigerator at about 10 C., since vaccine prepared a year ago still possesses about the same infectivity for the monkey and the same vaccinogenic activity. In order to render different vaccines comparable in attenuated virus and immunizing activity, they are now prepared of mixtures of from ten to twenty cords taken only from monkeys that have been severely paralyzed.

In the preparation of the vaccine due care must be exercised against contamination of the cords in removal and the preparation of finely divided suspensions. But it is our custom to place the cords in 50 per cent chemically pure glycerol in sterile saline solution for at least a month before use and under the circumstances the great majority of vaccines are found to be sterile on careful bacteriologic examination by culture.
